There are a number of functional differences between oxidized and reduced thioredoxin that are not due entirely to the presence or absence of thiol groups. Reduced thioredoxin is required for the assembly of filamentous bacteriophages^{30,31} and is an essential subunit of the DNA polymerase induced by T7 phage.³² Oxidized thioredoxin does not function in these systems. Mutants where one or both Cys residues are replaced with serine (Ser) or alanine (Ala) are partially functional,^{31,33} suggesting some structural or conformational difference between the two forms that can be differentiated in the phage systems. The extremely small structural differences between the two forms of thioredoxin is illustrated in Figure 1. Indeed, the only significant difference appears to be a slight change in the backbone configuration at the active site due to the change in position of the reduced sulfur of Cys-32,⁸ as shown in Figure 2. In the absence of a strongly marked change in the structure, the difference may lie in the relative mobility of the polypeptide chain in the vicinity

of the active site. Backbone dynamics of both oxidized and reduced thioredoxin were studied using ¹⁵N relaxation²⁴ and revealed a significant difference in the local flexibility of several of the loops that abut the active site. In particular, the sequence that precedes the highly conserved *cis*-Pro at position 76 is more flexible in reduced thioredoxin, suggesting that certain structural states may be kinetically accessible to reduced thioredoxin but not to the oxidized form due to the constraint imposed by the disulfide bond. This interpretation is borne out by a comparison of the rates of amide proton hydrogen exchange in the two forms of the protein,³⁴ which indicate a significantly greater protection in the active site region in oxidized thioredoxin, consistent with lower flexibility of the polypeptide chain. If one or more of these low-energy states was required for thioredoxin function in the filamentous and T7 phage systems, then reduced thioredoxin would be functional and the oxidized form would not. A recent NMR study of a double Cys-to-Ser mutant of *E. coli* thioredoxin²⁷ revealed that its behavior most closely resembled reduced rather than oxidized thioredoxin, consistent with these ideas and with previous functional studies of mutants.³¹

3 NMR OF HUMAN THIOREDOXIN

3.1 Solution Conditions for NMR

The thioredoxin cloned from human T-lymphocytes (105 amino acids) is approximately 25% homologous with the *E. coli* protein, mainly in the active site region.³⁵ Reduced human thioredoxin is soluble to at least 2 mM and solutions prepared

Figure 2 Stereo superposition (on the backbone of the entire molecule, residues 4–107, as in Figure 1) of the active site, including selected side chains, for 20 structures each of reduced (yellow) and oxidized (blue) thioredoxin. The disulfide bond is indicated by the hatched red and black bars, and the positions of the Cys sulfur atoms in reduced thioredoxin are shown by yellow spheres. (Reproduced by permission from Jeng et al.⁸)

in 100–150 mM phosphate buffer containing 0.2 mM DTT under argon appear to be stable at pH 7.0 or 5.5 for at least 2 months, over a temperature range of 4–50 °C.³⁶ Solubility is reduced at pH values below 5.6.³⁷ Only the reduced form of unmodified human thioredoxin has so far been studied by NMR, because of the presence of three Cys residues in addition to the two in the active site. The presence of these additional thiol groups causes problems with aggregation of the protein upon oxidation. The recombinant human thioredoxin isolated from an *E. coli* expression system is heterogeneous at the N-terminus, with about 30% of the protein containing an extra methionine residue,³⁶ although the N-terminal methionine is processed more efficiently during bacterial growth in minimal media.³⁸ A triple Cys-to-Ala mutant of human thioredoxin has been constructed to allow NMR studies of both oxidation states of human thioredoxin.³⁹

3.2 Resonance Assignments and Structure Determination

The ¹H resonances of reduced human thioredoxin were initially assigned and a description of the secondary structure was obtained using ¹H 2D methods.³⁶ Extensive ¹⁵N assignments and coupling constant measurements have been made for reduced human thioredoxin,³⁸ and a high-resolution structure has been calculated.⁹ A family of NMR solution structures of reduced human thioredoxin (Figure 3) were calculated using a hybrid distance geometry–simulated annealing method⁹ with 1294 interresidue and 689 intraresidue distance restraints obtained from NOESY and ¹⁵N heteronuclear multiple quantum coherence (HMQC)–NOESY experiments and 241 torsion angle restraints obtained from coupling constants. Proton and ¹⁵N resonance assignments have also been made for the reduced form of a triple mutant of human thioredoxin, in which the three Cys residues other than those in the active site have been mutated to Ala residues,³⁹ and structures have been calculated for the oxidized and reduced forms of this mutant¹⁰ using 2571 distance restraints, 273 torsion angle restraints, and 89 ³J(HN-α) coupling constant restraints for the reduced form, and 2649 distance restraints, 278 torsion angle restraints, and 91 ³J(HN-α) coupling constant restraints for the oxidized form. The backbone atomic rms deviations from the mean structure were 0.19 Å and 0.18 Å respectively for 40 structures of reduced and oxidized mutant thioredoxin.¹⁰ The

Figure 3 Stereo view (approximately the same view as Figure 1) showing the best-fit superpositions of the backbone (N, C-α, and C) atoms of 33 NMR solution structures of reduced human thioredoxin obtained by a distance geometry–simulated annealing method. (Reproduced by permission from Forman-Kay et al.⁹)

structure consists of a 5-stranded twisted β -sheet surrounded by four α -helices and the overall structure is similar to those of *E. coli* thioredoxins.^{5,7} The major differences between the thioredoxins from these two different sources is in helices α_1 and α_3 , which are longer and more regular in human thioredoxin. The active site conformations are all very similar, as would be expected from the high degree of sequence homology in this region.

3.3 Bound Water Molecules in the Structure of Human Thioredoxin

The positions of relatively tightly bound water molecules in the structure of reduced human thioredoxin have been determined using 3D ¹H–¹⁵N ROESY–HMQC spectroscopy.⁴⁰ A number of backbone amide protons are in close proximity to a total of four best-fit bound water molecules in structures recalculated to include them. Two of the water molecules could be located in fairly tight families, one in the β -bulge between strands 4 and 5 of the β -sheet and one associated with the C-terminal ends of the α_2 and α_4 helices. Of the other two water molecules, one occupies two positions near the loop between α_1 and β_2 and the other occupies two positions close to the N-terminus of α_2 , near the active site. Several of the positions found for the bound water molecules in the solution structure of reduced human thioredoxin⁴⁰ are similar to those found in the X-ray crystal structure of oxidized *E. coli* thioredoxin.⁵

3.4 Electrostatics and Redox Function in Human Thioredoxin

An extensive study of the pH-dependent behavior of reduced human thioredoxin was made using ¹H and ¹⁵N NMR spectroscopy.³⁷ Inclusion of measurements on solutions of pH lower than 5.6 allowed determination of the pK_a values of aspartate and glutamate side chains, although many of the titration curves exhibit complex behavior due to the effects of interacting titrating groups. Unlike *E. coli* thioredoxin,¹⁷ no clear-cut effect of the titration of the buried carboxyl side chain of Asp-26 was observed, and the pK_a of the thiol of Cys-32 was measured to be 6.3, lower than the value for *E. coli* thioredoxin. The anomalously low pK_a for the Cys-32 thiol was attributed³⁷ to an interaction of the S-γ atom of Cys-32 with the amide group of Cys-9 seen in the solution structure of reduced human thioredoxin.⁹

4 NMR OF *ESCHERICHIA COLI* GLUTAREDOXIN

4.1 Solution Conditions for NMR

E. coli glutaredoxin (85 residues, *M_r* ~10 000) is a heat-stable acidic protein which reacts with glutathione and is responsible for mediating many glutathione-dependent redox functions in the cell. There is very little sequence homology between *E. coli* glutaredoxin and thioredoxin, although both contain an active site disulfide/dithiol group. The solution conditions required for NMR studies of glutaredoxin are less than optimal for structure determination.⁴¹ Oxidized

glutaredoxin is insoluble at pH values below 5.5 and the NMR spectrum shows evidence of aggregation at pH 6.0. The protein appears to be stable and monomeric at pH 7.0 and 28 °C, at a concentration of 2.5 mM in 50 mM phosphate buffer. Reduced glutaredoxin is prepared from the oxidized form of the protein at 4 °C by the addition of DTT followed by buffer exchange in an ultrafiltration cell.¹² Final solution conditions were 3 mM protein in 50 mM phosphate, pH 7.0, 28 °C.

4.2 Resonance Assignments and Structure Determination

Nearly complete resonance assignments have been made for oxidized⁴¹ and reduced¹² *E. coli* glutaredoxin, using mainly ¹H 2D methods, with the addition of 3D ¹⁵N NOESY spectra for the resolution of ambiguities in NOE assignments and for measurement of ³J(HN- α) coupling constants. Initial NMR spectra showed some heterogeneity, as glutaredoxin

is apparently susceptible to proteolysis; this problem was overcome by the use of protease inhibitors.⁴¹ Additional heterogeneity in the NMR spectra of oxidized glutaredoxin was also due to the presence of about 10% of a form elongated at the N-terminus or to conformational isomerism.⁴¹ No conformational heterogeneity was reported for reduced glutaredoxin.¹² Three-dimensional structures were calculated for both forms of glutaredoxin using the program DIANA followed by simulated annealing. For oxidized glutaredoxin, 563 interresidue and 219 intraresidue distance constraints and 74 dihedral angle constraints were used.¹³ For reduced glutaredoxin, 402 interresidue and 221 intraresidue distance constraints and 191 dihedral angle constraints were used.¹² The structure of glutaredoxin, shown in Figure 4, consists of a 4-stranded β -sheet and three helices, and is very similar in both oxidized and reduced forms of the protein.¹³ Exchange rates of slowly exchanging amide protons are similar, indicating similar hydrogen-bonding patterns, but

Figure 4 Stereo views of the 20 conformers used to represent the solution structure of (a) reduced and (b) oxidized *E. coli* glutaredoxin obtained using the program DIANA followed by simulated annealing. The complete polypeptide backbone from residues 1 to 85 is shown. The conformers 2–20 were superimposed with conformer 1 (which has the smallest residual violations) for pairwise minimal rms deviation of the backbone atoms N, C- α , and C' of residues 1–8, 13–43, and 60–83. The active site (residues 11–14) is at the top right of the structure. (Reproduced by permission from (a) Sodano et al.¹² and (b) Xia et al.¹³)

differences in local dynamics are evident near the active site and the C-terminal α -helix.¹³ A comparison of Figures 1–4 shows that, despite the low sequence homology between glutaredoxin and thioredoxin, the overall folds of thioredoxin and glutaredoxin are quite similar.

4.3 Structure of a Mixed Disulfide Complex of Glutathione and Glutaredoxin

As for thioredoxin, the mechanism of thiol–disulfide exchange of glutaredoxin was thought to proceed via a mixed disulfide intermediate between one of the active site thiols and a molecule of glutathione.⁴² In order to probe the structure of such an intermediate, a mutant glutaredoxin was prepared with one of the active site cysteines, Cys-14, substituted by Ser. The physiological substrate, glutathione, could then be bound to the remaining cysteine, Cys-11, forming a mixed disulfide which ought to have the same structure as that of the wild-type, but which is stable since reaction of the second thiol (now a Ser) with a second molecule of glutathione and release of the oxidized glutathione dimer is not possible. The C14 → S glutaredoxin mutant and the mixed disulfide complex with glutathione have been prepared and characterized by NMR,⁴² and the structure of the complex has recently been reported.⁴³ Nitrogen-15 NMR studies⁴² confirmed that the glutathione molecule is attached via a disulfide bond to Cys-11, and the structure shows that it lies along a shallow cleft in the protein that includes a number of hydrophobic residues.⁴³

1 BACKGROUND

The fundamental magnetic properties of tritium (^3H) were first reported in 1947^{1–3} in a series of NMR measurements which demonstrated the triton to be a spin- $\frac{1}{2}$ nucleus, with a positive magnetic moment about 6.66% larger than that of the proton. Despite the fact that these measurements established tritium as the most sensitive NMR-active nucleus, very little research was conducted over the next two decades. In short, we have found only 24 reports of tritium spectra in the first 30 years, and 14 of those were published in the period 1974–76. The lack of activity in the early years of tritium NMR development is readily rationalized—tritium is a radioactive nucleus and, with the limited sensitivity of early spectrometers, the quantities required to make the 1947 measurements were enormous. [No specific details of sample sizes were given, but 50 μL of HTO with 50% abundance of ^3H contains ca. 3000 GBq of radioactivity, and we estimate that the samples must have been of this order, i.e. 1850–18 500 GBq (50–500 Ci).] Hence, applications were limited to US National Laboratories, where facilities existed for obtaining and handling large quantities of tritium.

The first liquids ^3H NMR spectrum other than HTO was described in 1964,⁴ and set several important precedents for the newly developing field: (i) samples required large amounts of tritium (ca. 370 GBq in this instance); (ii) instrumental modification for ^3H detection was simple; (iii) proton–tritium couplings were obvious and readily measured; and (iv) the labeling pattern (or percentage of ^3H in various positions) was accessible from the spectrum. The sample used in this experiment was ethylbenzene prepared by metal-catalyzed reduction of phenylacetylene with tritium gas, and interestingly, the integrated ratio of methylene to methyl tritium was 1:1.5, not 1:1 as predicted. This result established high-resolution ^3H NMR as the tool of choice for analysis of tritiated products. The ‘nontextbook’ labeling pattern would have been difficult to detect and almost certainly overlooked using the conventional methods of the time, and incorrect assumptions about the labeling pattern would have affected downstream uses of the product. Indeed, biochemical applications of tritium have been slow to recover from the poorly characterized materials used in the 1950s and 1960s, when ^3H NMR was not available for product analysis.

Such demonstrations of the power of ^3H NMR spectroscopy led to a renewed interest in technical development in the late

1960s and early 1970s. Fortunately, the resurgence coincided with advances in instrumentation that allowed many other low abundance and/or low sensitivity nuclei to be routinely observed. This revolution in NMR spectrometer sensitivity was crucial. Since tritium sensitivity is > 75 -times that of ^{13}C , the ability to collect ^{13}C spectra at natural abundance clearly implies that tritium spectra could be obtained at the very low ^3H concentrations necessary to ensure the technique is safe and accessible to laboratories around the world. During this period, the sample requirement of 370–3700 GBq was drastically reduced to the range of 3.7–3700 MBq, depending on the complexity of the signals and the S/N level required. Of course, tritium detection by NMR still suffers from the inherent insensitivity of the technique, and some perspective can be gained from the fact that liquid scintillation counting (LSC) techniques can detect tritium at a level 10^{-7} lower than the highest field spectrometers of today. Yet, the detailed information which NMR yields about the chemical and magnetic environment of the nuclei makes this loss of sensitivity easy to justify.

The most influential force in the promotion of ^3H NMR spectroscopy as a routine research tool came from a fruitful collaboration between the University of Surrey and Amersham International. The early published work (1971–76) concentrated on methodology and proof of principle, and in the late 1970s a host of applications were reported. A number of other groups adopted the ^3H NMR approach, and by 1985 the Surrey group was able to publish an excellent compilation of techniques and results, describing a mature field.⁵ In this article, we will discuss the major features of ^3H NMR spectroscopy, and address the more recent, popular, and significant chemical applications.

2 SAFETY

Tritium is the very rare, but naturally occurring, radioactive isotope of hydrogen. It is a pure β -emitter and its 12.4 year half-life is convenient for most chemical or biological experiments. In Table 1 we list a variety of chemical and physical properties of tritium and elementary tritiated compounds.

As mentioned above, the large amounts of tritium necessary for early experiments made containment of tritiated NMR samples a point of major concern, and a number of convenient containment systems have evolved.⁵ Since tritium is a ‘soft’ β emitter, i.e. the energy of the β particle associated with its radioactive decay has very little penetrating power (Table 1, $E_{\text{max}} = 18.6 \text{ keV}$, $6 \mu\text{m}$ range in water), it is readily contained by a thin surface of plastic, Teflon, or glass. The major hazard is from ingestion, so care should be taken to keep samples sealed and clean on the exterior. We favor a double encapsulation approach using either a 3-mm glass tube inside a regular NMR tube, or a capped Teflon liner inside a sealed glass tube. These components are all commercially available.

Since the number of tritium nuclei needed for NMR detection exceeds that required for liquid scintillation counting by a factor of ca. 10^7 , the monitoring of equipment or personnel for contamination is readily accomplished by standard radiochemical techniques. At the minimum level readily detectable by liquid scintillation counting (LSC) (37 Bq L^{-1}) in a conventional urine analysis, the radiation exposure for an individual is less than 0.001 mSv y^{-1} . The sensitivity

Table 1 General Physical and Chemical Data for Tritium, and Common Radioactivity Units^a

Production	${}^6\text{Li}(n, \alpha){}^3\text{H}$
Radiation	β (100%); range = 4.5–6 mm in air, 6 μm in H_2O
β Energy	$E_{\text{max}} = 18.6 \text{ keV}$, $E_{\text{mean}} = 5.7 \text{ keV}$
Radioactive half-life	12.43 y (4540 d)
Biological half-life	ca. 10 d
Decay product	${}^3\text{He}$
Maximum specific activity	1064 GBq milliatom ⁻¹ (28.76 Ci milliatom ⁻¹)
Detection limit (in 24 h): LSC	0.037 Bq = 2.09×10^7 atoms (ca. 0.1 fmol)
NMR	1064 kBq = 6.02×10^{14} atoms (ca. 1 nmol)
Diameter of tritium atom (approx.)	1.1 Å
Volume of 37 GBq (1 Ci) of tritium gas at standard temperature and pressure	0.385 mL
Radiation produced by 37 MBq (1 mCi) in a man (70 kg = 40 L, i.e. 25 $\mu\text{Ci L}^{-1}$)	0.044 mSv d ⁻¹ (= 4.4 mrem d ⁻¹ , or 1.6 rem y ⁻¹)
Density, triple point, and boiling point of isotopic water molecules	H_2O : 1.000 g mL ⁻¹ ; 0.01°C; 100.00°C D_2O : 1.106 g mL ⁻¹ ; 3.82°C; 101.42°C T_2O : 1.214 g mL ⁻¹ ; 4.49°C; 101.51°C
Tritium content of pure T_2O at STP	117.4 TBq mL ⁻¹ (3173 Ci mL ⁻¹) 96.7 TBq g ⁻¹ (2614 Ci g ⁻¹)

^a37 gigabecquerels (GBq) = 1 curie (Ci) = 3.7×10^{10} disintegrations per second; 1 gray (Gy) = 10 000 erg g⁻¹ = 100 rad (units of absorbed dose); 1 sievert (Sv) = 100 rem (units of radiation exposure).

of LSC thus provides a level of detection well below the average exposure from background, medical, and terrestrial sources (3 mSv y⁻¹) or the current recommendation for a US Department of Energy radiation worker (<20 mSv y⁻¹). In addition, tritium uptake in the body is cleared as tritiated water (HTO) with a 10 day biological half-life, and this period can be drastically reduced by increasing fluid intake or by diuretics (e.g. water, beer, or coffee).

The hazards associated with analyzing ${}^3\text{H}$ samples are real, but have been grossly overemphasized in the past. A rational assessment of the risks involved is in order. Tritium is readily contained and is physiologically benign at the levels used in most high-resolution NMR experiments. When making a benefit/hazard judgement of conducting research on a 2220 MBq (60 mCi) sample contained as described above, it is reasonable to remember that safety lights in aircraft contain up to 370 GBq (10 Ci) of tritium, a marine compass may have as much as 28 GBq (0.75 Ci), and commonly available night sights for rifles contain 2 GBq (50 mCi) of tritium. The spectroscopist may be at greater risk from the lock solvent or other chemical entity in the sample than from the radioactivity, e.g. in a 0.25 mL sample containing 2220 MBq of a tritiated compound in C_6D_6 , there are 2 μmol of ${}^3\text{H}$ but 2.75 mmol of benzene. It is clearly less hazardous to handle a well-contained tritium sample than milligram quantities of neurotoxins and other biologically active compounds routinely analyzed in normal glass NMR tubes in many laboratories.

In summary, the handling and health physics of analyzing tritiated samples is an important but trivially solved consideration, allowing ${}^3\text{H}$ NMR spectroscopy to be readily executed in most laboratories having a pulsed Fourier transform NMR spectrometer.

3 FEATURES AND PARAMETERS

The characteristics of ${}^3\text{H}$ are compared with other common NMR active nuclei in Table 2. Tritium enjoys all the spectral advantages normally associated with spin- $\frac{1}{2}$ nuclei of high γ :

narrow lines, high sensitivity, and good dispersion. A brief perusal of Table 2 indicates the strong similarity between triton and proton magnetic properties, with tritium having slightly higher sensitivity and dispersion, and similar relaxation characteristics. The similarity between nuclei extends to chemical shifts, allowing one to use the extensive library of proton chemical shifts when making tritium resonance assignments. Since tritium also has extremely low natural abundance, spectra are free of background signals and this, combined with the a priori knowledge of chemical shifts from analogous protons, makes assignment of tritium spectra particularly straightforward.

Many of the favorable properties of tritium are illustrated in the spectra in Figure 1, where a comparison of proton, deuterium, and tritium NMR spectra of labeled glucose is shown. The superior resolution and dispersion of tritium over deuterium, a spin-1 nucleus, is obvious. Note that this labeled molecule is low molecular weight, and the line broadening of deuterium signals for larger molecules is even more striking, hence eliminating deuterium NMR as a useful technique for the structural analysis of large molecules in solution. In addition, since the dominant relaxation mechanism for deuterium is quadrupolar, NOE determinations are impossible, and sensitivity in saturation transfer is reduced due to rapid spin-lattice relaxation. In contrast, tritium analysis greatly simplifies the proton spectrum in Figure 1(a), particularly around the solvent where a less fortuitous proton chemical shift (or sample temperature) would have completely obscured one of the glucose signals under the HDO peak. Even in H_2O , tritium spectra require no solvent suppression and are much more easily assigned than the generally more crowded proton analog.

To understand the quantities involved in a tritium NMR experiment, one must be aware of the common units and conversion factors which are listed in Table 1. One of the most important benchmarks is that complete replacement of hydrogen by tritium in one position of a molecule gives a specific activity (SA) of 1064 GBq mmol⁻¹ (28.76 Ci mmol⁻¹). Obviously, for lower percentages of tritium replacement the SA value is proportionately reduced and this relationship,

Table 2 NMR Properties of ^3H and Common NMR Nuclei^a

Nucleus	Natural abundance	Spin	γ	Resonant frequency	Relative sensitivity ^b
^1H	99.984	$\frac{1}{2}$	26.7510	300.13	1.00
^2H	0.0156	1	4.1064	46.07	9.65×10^{-3}

combined with a knowledge of the total number of millimoles of labeled substrate, readily yields the amount of radioactivity involved in the experiment.

3.1 Chemical Shifts and Referencing

Early measurements established that the ratios of nuclear screenings among the hydrogen isotopes was very close to unity. This implies that the chemical shift for a triton is essentially identical to that of a proton or deuteron in the analogous molecular environment. Thus tritium spectra can be referenced to, say, monotritiated TMS and chemical shifts will be nearly identical to proton chemical shifts. Since the tritium/proton Larmor frequency ratio is very well determined for TMS⁶ ($1.066\,639\,739 \pm 2 \times 10^{-9}$), in practice it is not necessary to add a tritiated reference material to a sample to achieve accurate referencing. Instead, a simple measurement of the *proton* frequency of a reference material and multiplication by the figure above gives the tritium resonance frequency for the reference. This procedure is known as ghost referencing. Some care must be taken in very precise work when using ghost referencing because more careful studies of the Larmor frequency ratio for a variety of tritium-labeled materials^{6,7} have shown that nuclear screenings are not identical, but vary slightly with carbon–hydrogen (tritium) bond hybridization. Thus, when referencing tritiated methyl groups a TMS ghost may be appropriate, but a tritiated phenyl position is more accurately referenced by a phenyl proton and a slightly different Larmor frequency ratio. These differences are usually so small that they do not interfere with routine analysis, and are not discerned in a wide display (0–6 ppm), such as that in Figure 1.

3.2 Coupling Constants and Isotope Effects

Coupling constants between tritium and other nuclei may be calculated from the analogous proton coupling constants. In

particular, $J(\text{T,T})$ and $J(\text{T,H})$ are given by the relationships in Table 2, i.e. tritium–proton spin–spin coupling constants may be calculated as ca. 6.664% larger than the analogous proton constant. There is a small isotope effect on the coupling constant,⁸ and measurements have been reported for tritium coupled to a number of other nuclei besides protons including carbon, tin, silicon, and boron.

Although there are isotope effects, measurement of a $J(\text{T,H})$ value is still an accurate way of predicting a proton–proton coupling constant, since the calculation involves division by 1.06664 rather than multiplication by 6.5144, as required by prediction from $J(\text{D,H})$. For isochronous protons (e.g. methyl protons having degenerate chemical shifts), measurement of the $J(\text{T,H})$ value readily yields a usually ‘invisible’ coupling constant (see Figure 2, below).

Besides the small isotope effects on nuclear screening and on coupling constants discussed above, there are also more commonly observed isotope effects on tritium chemical shifts caused by substitution of a heavy isotope in place of a proton. These are largest and therefore most easily observed when a geminal proton is replaced by a triton. This effect was first reported in analyses of highly tritiated methyl groups,⁹ where the R-CT_3 singlet was resolved from the $\text{R-CT}_2\text{H}$ doublet in the proton coupled tritium spectrum. The proton-decoupled spectrum was used to show that this primary isotope effect is ca. 0.025 ppm (i.e. 2.4 Hz at 96 MHz).

Figure 2 illustrates tritium isotope effects on chemical shifts and demonstrates how the methyl $J(\text{H,H})$ may be calculated from measured $J(\text{T,H})$ values, as discussed above. A sample of *m*-xylene was tritium-labeled by Raney nickel catalyzed exchange with T_2 , which is known to give almost exclusive methyl tritiation. All three tritio-methyl species are produced, as shown in the proton-decoupled tritium spectrum in Figure 2(a), where these species are separated by the primary isotope effect ($\Delta\delta$) on the tritium chemical shift. At 320 MHz, tritium signals from methyl groups have a proton–tritium coupling constant which is double $\Delta\delta$, so that the proton-coupled tritium spectrum in Figure 2(b) has a deceptively simple

Figure 1 Hydrogen NMR spectra of D-glucose in water. (a) Proton spectrum of C-1 tritiated D-glucose; the large peak is due to HDO. (b) Proton decoupled deuterium NMR spectrum of C-1 deuterated glucose; DMSO is an integration marker. (c) Proton-coupled tritium spectrum of C-1 tritiated glucose, labeled by the same catalytic technique as in (b)

appearance. The splitting patterns are shown on the figure, and our assignments are readily verified by integration of the signals in each of the spectra. The methyl $J(\text{H},\text{H})$ for *m*-xylene methyl groups may be calculated from the observed $J(\text{T},\text{H})$ value.

Secondary tritium isotope effects on chemical shifts have also been well quantified,¹⁰ and the primary deuterium isotope effect on tritium chemical shifts is also easily measured (Table 2).

3.3 Tritium NMR Intensity and the NOE

One of the major advantages of tritium NMR spectroscopy is that the labeling pattern in a sample may be determined without the time-consuming and laborious degradative determinations previously required.¹¹ Indeed, a tritium spectrum gives nondestructive, quantitative information on relative tritium abundance at different sites in a molecule. Of course, care must be exercised in any measurement of NMR peak intensities so that accumulation of the data does not *differentially* affect the various peaks. When proton decoupling is used, for example, the tritium intensities will be affected by the Nuclear Overhauser Effect (NOE). Because of the frequent

Figure 2 Deceptively simple tritium NMR spectra in C_6D_6 of *m*-xylene labeled by T_2 gas exchange over Raney nickel catalyst. (a) Proton-decoupled tritium spectrum showing peaks for $\text{R}-\text{CH}_2\text{T}$, $\text{R}-\text{CHT}_2$, and $\text{R}-\text{CT}_3$ species separated by $\Delta\delta = 0.025 \pm 0.001$ ppm (7.89 ± 0.21 Hz at 7.1 T). (b) Proton-coupled spectrum showing overlapped tritium multiplets separated by $J(\text{H},\text{T}) = 15.58 \pm 0.21$ Hz

use of proton decoupling in tritium experiments, the importance of this effect has been the subject of several studies and discussions.¹² While the maximum theoretical NOE enhancement to tritons from proton irradiation is 47%, the observed enhancements vary from 10–35%. More importantly, there are situations where differential NOEs may prejudice tritium spectral intensities, such as a labeled molecule with a high abundance of tritium in a position without neighboring protons and a second tritiated position which has many relaxation partners, and integrals should only be compared when these issues have been considered.

3.4 Relaxation

The similarity of tritium and proton nuclei means that their pathways for relaxation are nearly identical. A feature of tritium NMR is that the simple spectra allow straightforward relaxation measurements. The analogous measurements in proton spectra can be difficult due to spectral crowding, solvent suppression, or the complexity of the physical system. Hence tritium relaxation can be the more useful probe of molecular interactions. A classic example is the use of proton and tritium relaxation measurements combined with homo- and heteronuclear saturation transfer experiments to study the relaxation of water molecules in the presence of a macromolecular suspension.¹³ A rather simple suspension was created

by the formation of egg phosphatidylcholine/cholesterol lipid bilayers in solution. In a lipid suspension the water can exist in two distinct environments, a 'free' state exhibiting bulk water properties, and a motionally hindered or 'bound' state that is associated with the lipid in a hydration shell. Nuclei in these populations relax differently. The free water has the familiar characteristics of small rapidly tumbling molecules in solution, while the bound water has an additional slow component of tumbling due to its association with the lipid. This lipid-induced hydrodynamic effect causes a more rapid relaxation in the bound state and the presence of two water populations with different relaxation rates makes the overall relaxation behavior of the water signal complex. In general, it will depend on a combination of processes including the hydrodynamic effect, chemical exchange between free and bound environments, and the dipolar interaction (cross relaxation).

In the investigation of these processes, tritium doped water was used to separate the exchange contribution from other relaxation processes in the heteronuclear tritium-proton experiments. The measurements made on this rather complicated system were thus simplified to an analysis of several single-line spectra using inversion-recovery and saturation transfer experiments. The results indicated that the dipolar interaction (in the spin diffusion limit) dominates the relaxation of the water, and two models of this limit were proposed which accurately predicted the results, including a rigid and dynamic description of the lattice in the lipid solution. A complete model of the relaxation behavior of water is very desirable since the difference in relaxation properties of free and bound water populations is the basis for contrast and tissue characterization techniques in magnetic resonance imaging.

4 APPLICATIONS

We will limit the discussion here to chemical applications: (i) analysis of labeled materials for chemical and radiochemical purity; (ii) reaction mechanisms and tritium NMR techniques; (iii) specific activity measurements; (iv) solution conformation, stereochemistry, and optical purity; (v) proton exchange studies; and (vi) miscellaneous tritium NMR studies. Biological applications of ^3H NMR, e.g. ligand binding, metabolism studies, etc., are discussed elsewhere (see *Tritium NMR in Biology*).

4.1 Analysis of Labeled Materials

The vast majority of reports involving ^3H NMR spectroscopy describe the products of tritium-labeling reactions, and in this application the technique is invaluable. Tritium NMR has been used extensively for the investigation of many tritium exchange techniques, including radiation-induced and acid-, base-, metal-, or zeolite-catalyzed reactions.¹⁴ In general, these techniques rely on the replacement of a hydrogen atom by a tritium (i.e. exchange) in the native structure, and give low specific activity products which may contain tritium in one of several distinct sites.

In contrast, high level tritium labeling usually involves a synthetic transformation such as dehalogenation, hydrogenation, or hydride reduction of a suitable precursor. Dehalogenation reactions are an attractive method for introducing tritium

into a compound, but surprisingly these reactions rarely give quantitative replacement of halogen by tritium, even when 100% T_2 gas is used. Our experience is that 10–30% of product molecules will incorporate adventitious hydrogen (^1H) rather than ^3H . In general, the shorter the reaction time, the less hydrogen incorporated (i.e. the higher the SA value obtained), and it is advisable to use an iodo derivative as the substrate since the facility of halogen removal is $\text{I} > \text{Br} > \text{Cl} > \text{F}$. Also, 1 equiv. of organic base (e.g. triethylamine) enhances the reaction rate and neutralizes the acid formed.

The power of tritium NMR in the analysis of a tritiodehalogenation reaction product is best illustrated by an example. Figure 3(a)–(e) show a full proton and ^3H NMR analysis of a peptide labeled by catalytic dehalogenation of the analogous 3,5-diiodotyrosyl peptide. The aromatic portion of the proton spectrum of the tritiated material [Figure 3(a)] shows ca. 15% proton intensity at the tyrosine 3 & 5 chemical shift, with the usual tyrosine 2 & 6 and Phe aromatic signals. Note that the splitting of the tyrosine 2 & 6 doublet reflects $J(\text{T},\text{H})$, not coupling to the 3 & 5 protons. The proton-coupled tritium spectrum in Figure 3(b) shows a clean doublet at the tyrosine 3 & 5 chemical shift for the incorporated tritium. Broadband decoupling of the protons yields the singlet tritium signal in Figure 3(c), as expected. Selective irradiation at the tritium tyrosine 3 & 5 frequency causes the tyrosine 2 & 6 doublet to collapse, as shown in the proton spectrum in Figure 3(d) [cf. Figure 3(a)]. Similarly, selective ^1H decoupling at the tyrosine 2 & 6 frequency yields a singlet tritium signal at the tyrosine 3 & 5 chemical shift [Figure 3(e)]. These experiments are readily performed and characterize the product beyond any doubt.

The other most common method for introducing high levels of tritium is catalytic hydrogenation of an unsaturated site on a suitable precursor. Interestingly, heterogeneous metal-catalyzed hydrogenation reactions often do not yield 'textbook' results, and it is remarkable that so few researchers are aware of these details, despite their repeated demonstration.⁵ Two effects contribute to the complicated mixture of isotopomers obtained from these reactions:¹⁰ (i) there is an inventory of hydrogen ($^1\text{H}_1$) in the catalyst, solvent, substrate, and reaction vessel which serves to **decrease** the maximum level of tritium which may be incorporated into the labeled material; and (ii) vinylic and allylic protons may undergo metal-catalyzed exchange prior to saturation of the multiple bond, thus leading to **increased** specific activity.¹⁵ As a result, the products of a hydrogenation reaction often have (a) lower than theoretical incorporation of tritium, (b) tritium in positions remote from the original site of unsaturation, and (c) unequal amounts of tritium on each side of the original multiple bond.

When ^3H NMR is used to analyze the products of both heterogeneous and homogeneous catalysis of an identical reduction, the complexities of heterogeneous catalysis are clear. Such a comparison of tritiation techniques for the labeling of an unsaturated phospholipid molecule is shown in Figure 4. All the problems described above for heterogeneous catalysis complicate the spectrum shown in Figure 4(a), including small amounts of tritium incorporated at the positions adjacent to the double bond. In contrast, the product of the homogeneous tritiation using Wilkinson's catalyst [Figure 4(b)] shows clean addition of tritium, with a 1:1 ratio at the C-7 and C-8 positions. A ^3H – ^3H COSY analysis of this product [Figure 4(c)] showed that the two

Figure 3 Proton and tritium NMR spectra in D_2O of a peptide labeled by catalytic tritio-dehalogenation of the appropriate diiodotyrosyl peptide. (a) Aromatic region of the proton spectrum showing signals from the phenylalanine residue and a clean doublet from the tyrosine 2 and 6 protons. Residual proton signals are obvious from the tyrosine 3 and 5 position. (b) Tritium spectrum showing the doublet of the tyrosine 3 and 5 tritons coupled to the 2/6 protons. (c) Proton-decoupled tritium spectrum showing the tritium singlet from the 3 & 5 tritium atoms. (e) Selectively proton decoupled tritium spectrum, with irradiation only at the tyrosine 2 & 6 doublet

expected diastereotopic products were obtained, in a 1:1 ratio.¹⁶ Although this tritium analysis shows that Wilkinson's catalyst gives a very clean product, it is not applicable in all circumstances. Such mundane issues as sample solubility and recovery of the labeled material from the reaction mixture often affect the decision of which catalyst is used. Heterogeneous catalysts have the advantages that they are tolerant of a variety of solvent systems and are easily filtered away after the reaction. Wilkinson's catalyst is usually employed as a benzene solution and may not perform well in a binary mixture if the substrate is insoluble in benzene. In addition, Wilkinson's catalyst is designed to form an intimate mixture with the substrate, and postreaction separation steps need to be optimized for each new substrate.

4.2 Reaction Mechanisms and Tritium NMR Techniques

Tritium spectra are almost always simple, hence there has been no strong drive to apply more sophisticated NMR techniques to tritium analyses. However, the subtleties of exchange effects in heterogeneous catalysis and the complex products from enzymatic reactions often require careful interpretation, and such studies may be greatly enhanced by the use of modern multipulse approaches.

The following techniques have been applied to tritium analyses over the past decade: double quantum filtering, DEPT, 2D homonuclear COSY, 2D tritium/proton correlation, 2D J -resolved, and 2D NOESY and EXSY experiments. The NOESY and EXSY approaches have been used for macromolecular structure studies and are discussed elsewhere

Figure 4 Proton-decoupled tritium NMR spectra of a labeled phospholipid in D_2O . (a) Product of a heterogeneous catalytic hydrogenation reaction. (b) Product from catalytic hydrogenation in the presence of Wilkinson's catalyst. (c) $\{^1\text{H}\} {}^3\text{H}-{}^3\text{H}$ COSY of the product in (b)

Figure 5 Tritium NMR spectra of tritiated 3-indolepropionic acid in CD_3OD . (a) Proton-decoupled tritium spectrum of the product of a heterogeneous catalytic hydrogenation reaction using 15% T/H. (b) Double quantum filtered proton-decoupled tritium spectrum of the same product as shown in (a). The observed $J(\text{T},\text{T}) = 7.32 \pm 0.12 \text{ Hz}$, suggesting a $J(\text{H},\text{H})$ value of ca. 6.4 Hz

(see *Tritium NMR in Biology*). The pulse sequences we regard as most useful for analytical applications are the DQF and 2D J -resolved experiments. These have been used for detailed investigation of the 'nontextbook' results typically encountered in tritiation reactions, which are usually invisible in the corresponding reaction with ${}^1\text{H}_2$. Hence tritiation and tritium NMR spectroscopy provide an excellent approach for investigation of these imperfectly understood reaction mechanisms, as discussed below.

The research staff at Berkeley routinely use a mixture of 5–15% T_2 in H_2 for exploratory labeling reactions and in a training program. In the hydrogenation of 3-indoleacrylic acid using a 10% Pd/C catalyst and 15% T_2 in H_2 gas, simple statistics predict that 2.25% of labeled 3-indolepropionic acid product molecules will contain two ${}^3\text{H}$ atoms, 25.5% will have a tritium at one carbon or the other, and 72.25% will contain no tritium. The ${}^1\text{H}$ -decoupled tritium NMR spectrum in Figure 5(a) shows several features: (i) the large singlet signals arise from molecules containing one tritium atom, and it is obvious that unequal amounts of ${}^3\text{H}$ are incorporated across the double bond, and (ii) one signal from a small doublet can be discerned at the base of each singlet (asterisked), presumably arising from the doubly tritiated species. The unequal substitution pattern in the singly tritiated species is thought to arise from

exchange at those carbons prior to saturation of the double bond, and tritium NMR represents the best method for the further study of the mechanism of such exchange.¹⁵ The doubly tritiated species can be observed simply and directly by the application of a familiar multiple pulse technique, a double quantum filtered (DQF) experiment. The results of the DQF experiment on this molecule are remarkably clean, as shown in Figure 5(b). The spectrum is simple because the doubly tritiated species is the only one present with tritium homonuclear double quantum transitions, and is further simplified because all couplings to protons are heteronuclear and have been removed by broadband decoupling. This result has tremendous potential for the study of the mechanism of this type of addition and would not have been possible without the use of tritium NMR. Clearly this unique ability to separate labeled species and perform careful analysis of complex mixtures of isotopomers resulting from a theoretically simple tritiation reaction is essential for understanding the mechanism of these reactions.

Two-dimensional J -resolved ^3H NMR¹⁰ can be an even more powerful tool for the analysis of complex isotopic mixtures. β -Methylstyrene was tritiated by catalytic reduction with 100% T_2 over 5% Pd/C catalyst, to give highly tritiated n -propylbenzene with ca. 40% of the tritium on the α -methylene carbon, 50% on the β -methylene, and 10% in the methyl group. In addition, all of the multiplets for these tritiated positions showed a complex structure, not at all like the simple doublet of doublets which might have been proposed assuming clean addition of a tritium atom to each end of the double bond.

The methyl region of the proton-decoupled tritium J -resolved analysis of this sample (Figure 6) provided most

insight into the species giving rise to the various signals. There is a repeating and slightly overlapped singlet–doublet–triplet pattern, with each repetition moved successively to lower frequency by ^3H isotope effects. These first of these patterns (group A, Figure 6) is due to the species $\text{X}-\text{CH}_2-\text{CH}_2\text{T}$, singlet; $\text{X}-\text{CHT}-\text{CH}_2\text{T}$, doublet; and $\text{X}-\text{CT}_2-\text{CH}_2\text{T}$, triplet (species 1, 2, and 3), and the small change in chemical shift between these signals is the secondary tritium isotope effect induced by addition of a T at the β - CH_2 . There are similar patterns for the $-\text{CHT}_2$ (B) and $-\text{CT}_3$ (C) methyl species, successively moved to lower frequency by the primary tritium isotope effect on the methyl chemical shift. Inspection of several slices along the ω_2 dimension (submatrix, or .smx plots shown in Figure 6) show the relative abundance of each species in this mixture, and analysis of ω_1 slices allows us to extract all the $^3\text{H}-^3\text{H}$ coupling constants. Similar detailed analysis of the α - CH_2 and β - CH_2 regions of the J -resolved spectrum is also possible, and evidence was found for almost all of the 35 statistically possible, tritium-containing isotopomers. While the theoretical product, $\text{Ph}-\text{CHT}-\text{CHT}-\text{CH}_3$, was the most abundant species, the presence of another 34 tritiated isotopomers makes it clear that the mechanism of heterogeneous metal-catalyzed hydrogenation reactions is not as simple as commonly thought.

4.3 Specific Activity Measurements

The molar specific activity (i.e. radioactivity per unit weight) of tritium-labeled molecules is an important property, and tritium NMR may be used to determine this quantity.⁵ This approach is essential when the labeled material has no UV

Figure 6 The methyl section (0.68–0.93 ppm) of the contour plot of the proton-decoupled tritium J -resolved spectrum of n -propylbenzene, labeled by catalytic tritiation of β -methylstyrene. Sine-bell window functions were applied in both dimensions, $2k \times 512$ W transform, with magnitude calculation of peak intensities. The data were 'tilted' and 'symmetrized'

spectrum, or the high specific activity precludes weighing to determine sample concentration. An example of the latter was the determination of the SA value for a series of NaBT₄ preparations.¹⁷ Boron has two NMR active isotopes (¹⁰B, 20%, $I = 3$ and ¹¹B, 80%, $I = \frac{3}{2}$), so the proton spectrum of sodium borohydride in basic CD₃OD shows a large quartet (Na¹¹BH₄, $\delta = -0.168$ ppm, $J = 80.6$ Hz) and a small septet (Na¹⁰BH₄, $\delta = -0.166$ ppm, $J = 26.98$ Hz). The proton-decoupled tritium spectrum of exchange labeled NaBH(T)₄ shows a similar spectrum for each isotopomer, i.e. NaBH₃T, NaBH₂T₂, NaBHT₃, NaBT₄, shifted to lower frequency for each additional T. The multiplicity (redundancy) of the peaks is useful since peak overlap does not occur for all the species, and the isotopomer ratios may be compared between large quartet signals and the smaller septets. The amount of unlabeled (NaBH₄) material present was estimated by comparison with NaBH₃T signals in the proton spectrum. Knowing the mole ratio of all the isotopomers yields the SA value, and this property was compared for several production 'lots' of tritiated borohydride.

Even when determination of SA by UV spectroscopy and LSC counting, or by mass spectrometry, is possible, the NMR technique provides a useful cross check. In comparison to the sodium borohydride case above, a very simple example is given in Figure 7. Pinoline (6-methoxy-1,2,3,4-tetrahydro-9H-pyrido[3,4-*b*]indole) was labeled by catalytic hydrogenation of the unsaturated 3,4-dihydro analog. The product consisted of a mixture of three isotopomers containing zero, one, or two tritium atoms per molecule. Obviously, at the chemical shift of the C-1-methylene, one of these species has only a proton spectrum, one has a tritium spectrum, and one [R-CHT, $\delta = 4.39$ ppm, Figure 7(a) and (b)] has both a tritium and a proton NMR spectrum. In this case, the use of selective tritium [Figure 7(a)] or proton [Figure 7(b)] decoupling allows the observation of single lines for each of the isotopomers in the proton or tritium spectrum. Since the R-CHT signal occurs in both spectra, the molar ratio of the three species may be extracted from these spectra and the specific activity calculated.

4.4 Solution Conformation, Stereochemistry, and Optical Purity

Tritium NMR has been used to obtain the axial-equatorial conformational preference of tritium in [³H]cyclohexane.¹⁸ Tritium has the advantage of giving sharp and well-separated peaks that are well suited for high-accuracy integration at low temperatures, i.e. the peak separation in these experiments was ca. 150 Hz at 7.1 T, whereas the analogous deuterium experiment at 11.7 T gave a separation of only 36 Hz. [³H]Cyclohexane was made from cyclohexylmagnesium chloride in diethyl ether by the addition of HTO (5% tritium) followed by distillation of the tritiated product. A sample (ca. 0.9 GBq, 33 mCi) in CS₂ containing some CD₂Cl₂ for lock purposes was transferred into a standard thin-wall glass 5-mm NMR tube and ³H {¹H} NMR spectra were obtained at 320 MHz (300-MHz ¹H frequency). Narrow lines (ca. 2 Hz at halfheight) with good lineshapes were obtained at -88 °C by using the tritium FID as well as the ²H lock signal for shimming. For accurate integration it is essential that the base of the peaks be narrow and symmetrical, and that the baseline

Figure 7 Proton and tritium NMR spectra of tritiated pinoline in CD₃OD. (a) Selectively tritium-decoupled proton spectrum. (b) Selectively proton-decoupled tritium spectrum

is flat. A number of data sets, each consisting of the sum of 512 FIDs were acquired, several with the carrier at a higher frequency than the sample signals, some with the carrier at a lower frequency, and others with the carrier centered between the signals. The ¹³C satellites of both the axial and equatorial ³H signals ($\delta\nu = 0.471$ ppm) were visible in each set of spectra and gave $J(^{13}\text{C}, ^3\text{H}_{\text{ax}}) = 131.1$ Hz and $J(^{13}\text{C}, ^3\text{H}_{\text{eq}}) = 135.2$ Hz. Integration of the spectra showed that tritium prefers the equatorial over the axial site by about 46.9 J mol⁻¹ and a ³H EXSY experiment showed that the axial and equatorial tritium atoms are undergoing (slow) exchange at -88 °C. Conformational analysis by ³H NMR relaxation has also been used in enzyme ligand studies (see NT497-*Tritium NMR in Biology*).

The absolute stereochemistry of a tritium atom on a carbon may be determined by tritium NMR if there is another chiral center in the molecule. If this is not the case on the parent molecule, it can often be created by esterification or some other derivatization. This feature was exploited in analysis of tritiated ethanol produced by enzymatic oxidation of 'chiral ethane', i.e. CH₃-CHDT, as part of a study of the mechanism of methane monooxygenase.¹⁹ Tritium NMR analysis of the methylene region of the ethanol product showed signals from CH₃-CHT-OH and CH₃-CDT-OH, separated by the ²H isotope effect on the tritium chemical shift [Figure 8(a)]. Whereas this spectrum gives information on the relative rate of removal of an H or D atom in the oxidation process, it gives no stereochemical data. A simple derivatization with

Figure 8 Proton-decoupled tritium NMR spectra of the products from enzymatic oxidation of chiral ethane. (a) Ethanol in H_2O . (b) Derivatized ethanol in C_6D_6 , where $\text{R} = (2R)\text{-2-acetoxy-2-phenylethanoic acid}$

$(2R)\text{-2-acetoxy-2-phenylethanoic}$ (mandelic) acid yields ethyl mandelate, and the four possible species can be readily separated and quantitated by ^3H $\{^1\text{H}\}$ NMR, as shown in Figure 8(b). The *absolute* stereochemistry was previously established by a known synthesis of the deuterium-substituted molecules and proton NMR analysis.

Tritium NMR has been used to determine the optical purity of labeled materials. The use of a lanthanide shift reagent²⁰ or Pirkle's alcohol²¹ is a more general technique than the careful stereochemical determinations discussed above, and does not require the presence of an alcohol or amine functionality for derivatization to the appropriate ester or amide. This general approach is especially important for materials labeled at low tritium abundance because the optical properties of the bulk material may not be the same as the small subpopulation of labeled molecules.

4.5 Proton Exchange Studies

The NMR properties of tritium make it particularly well suited for in situ measurements of acid- and base-catalyzed proton exchange kinetics using tritium NMR spectroscopy.²² Despite the great sensitivity and simplicity of this approach,⁵ previous tritium NMR mechanistic studies of proton exchange have been confined to a static approach, i.e. the analysis of aliquots of a kinetic experiment.²³ In most circumstances, it is desirable to perform one-tube, accurate, kinetic experiments, especially for compounds which are only available in small amounts or have several exchanging positions with similar rates. Use of deuterium NMR spectroscopy, hampered by its low sensitivity and resolution, is inherently limited to initial

rates,²⁴ and if several positions are measured simultaneously, relative rates for the positions must lie within a small range. In contrast, tritium NMR spectroscopy allows one to measure the proton exchange kinetics of several compounds which may have similar rates or vary by a factor of 1000. Since tritium is a highly sensitive nucleus, the sample need not contain high levels of tritium for detection (especially compared with deuterium) and tritium therefore functions as a true tracer in the reaction kinetics. Only 20–180 MBq (0.5–5 mCi) per position ($1.5 \times 10^{-5}\%$ incorporation) is necessary for an adequate S/N ratio. This low tritium concentration also ensures the absence of tritium–tritium coupling, and the high γ and excellent relaxation characteristics of the nucleus lead to sharp resonance lines. The integrity of the reactant mixture may be monitored by proton NMR spectroscopy at any stage of the experiment. An inverse-gated proton-decoupling scheme may be used to ensure that single peaks are observed for each magnetic environment and that the relative peak integrals are not affected by NOE build-up. The quality of the kinetic data obtained by this technique suggests that it may be readily applied to other chemical proton-transfer systems.

As an example, this technique has been applied to the measurement of detritiation rates for the characterization of isotope effects. The Swain–Schaad relationship predicts that the deuterium and tritium isotope effects on the rate of a reaction are related as follows: $(k_{\text{H}}/k_{\text{D}})^x = k_{\text{H}}/k_{\text{T}}$. Theoretical calculations put x in the range 1.33–1.58, and a simple zero-point energy formulation of isotope effects gives $x = 1.44$. Deviations from this range have recently been used as evidence of tunneling in enzyme-catalyzed reactions, so the accuracy of experimental results in simple chemical systems is important. Such a simple system is the hydroxide ion-catalyzed enolization of acetone (a prototype ketone ionization reaction), but the originally published measurements give an anomalously low exponent, $x = 1.08$.²⁵ This exponent was based upon rates of detritiation of labeled acetone, which were determined by a technique that involved a difficult separation of acetone from water.

This reaction was reinvestigated²⁶ using tritium NMR to monitor the exchange of tritium between acetone and water in situ,²² thus avoiding the troublesome acetone–water separation. In NMR experiments using a range of base concentrations, the tritium signal from the acetone at $\delta = 2.1$ ppm was seen to decay while another resonance at $\delta = 4.7$ ppm, attributable to HTO, appeared (Figure 9). Least-squares fitting of the observed exponential rise and decay gave first-order rate constants that agreed well with each other.

When the NMR result was combined with k_{H} and a literature value of k_{D} determined by mass spectrometric measurements, it yielded $k_{\text{H}}/k_{\text{D}} = 7.2$ and $k_{\text{H}}/k_{\text{T}} = 19.2$. These isotope effects provide the Swain–Schaad exponent $x = 1.49 \pm 0.07$, which is in complete agreement with theory. Thus, tritium NMR provided a simple method for the measurement of an important exchange rate which was essentially inaccessible by chemical techniques.

4.6 Miscellaneous

Tritium NMR spectroscopy has been used in a number of other very specific chemical and physical investigations, most of which have been comprehensively reviewed elsewhere.⁵

Figure 9 A stacked plot of the proton-decoupled tritium NMR spectra of the base-catalyzed detritiation of acetone ($\delta = 2.1$ ppm) with exchange into the solvent (HTO, 4.7 ppm). The experimental parameters were: 500 μL , 0.04 M, NaOH; 5 μL , ^3H -acetone; $T = 298$ K; 120 transients; 100 experiments over 10.5 h (ca. 4-min interval for the first 50, then 8-min interval); spectrometer unlocked; $t = 0$ when the acetone was added, and the first spectrum was finished at $t = 20$ min. Seventy-seven spectra are plotted

These applications have included: (i) the observation of hydrogen-bonding effects on the chemical shift of proton versus tritium NMR signals; (ii) determination of solvent isotope effects and fractionation factors; (iii) aspects of radiation chemistry including sample radiolysis, studies of DNA hydration, and in situ production of labeled carbocations; (iv) investigations of labeled molecules in a liquid crystal environment; (v) solids tritium NMR and characterization of trapped gases in irradiated lithium hydride (tritide) samples;²⁷ and (vi) study of the origin of an anomalously large proton–proton coupling in transition metal polyhydrides.²⁸

5 CONCLUSION

We have discussed a wide range of applications where the use of tritium NMR has been useful, and some instances where it was essential. The similarity in NMR properties between protons and tritons means that many systems may be studied using either nucleus. Moreover, when proton systems become too complex, the spectral simplification of tritium spectroscopy suggests that tritium NMR should be considered. Radioactivity is the only issue hindering the universal application of tritium in many more general NMR studies.

Vicinal $^1\text{H}, ^1\text{H}$ Coupling Constants in Cyclic π -Systems

Harald Günther

University of Siegen, Germany

1 DISCUSSION

According to the Karplus theory of vicinal $^1\text{H}, ^1\text{H}$ coupling constants, i.e. $^3J(^1\text{H}, ^1\text{H})$, such parameters depend on the structural features of the corresponding HC–CH fragment (dihedral angle Φ , bond length R_{cc} , and HCC valence angles) as well as on the electronic effects of substituents.^{1,2} These results form the basis for numerous applications of ^1H NMR spectroscopy in organic, bio-organic, and organometallic chemistry.

While the dihedral angle dependence of $^3J(^1\text{H}, ^1\text{H})$ —the well-known *Karplus curve*—is one of the major tools in conformational analysis,³ structural research in the field of cyclic π -systems profits from the R_{cc} and valence angle dependence which dominates $^3J(^1\text{H}, ^1\text{H})$ values in planar unsaturated hydrocarbons, where $\Phi = 0^\circ$ for a *cis*-HC $_{\mu}$ –C $_{\nu}$ H arrangement and where substituents are absent. This aspect was first highlighted as a linear dependence between $^3J(^1\text{H}, ^1\text{H})_{\text{cis}}$ and the Hückel (HMO) π -bond order, $P_{\mu\nu}$, of the C $_{\mu}$ –C $_{\nu}$ bond was found for benzenoid aromatics⁴ and later extended to olefinic systems.^{5,6} At the same time, related correlations between $^3J(^1\text{H}, ^1\text{H})$ and the CC bond length $R_{\mu\nu}$ were established for aromatics⁷ and polyenes.⁸ An early application of $^3J(^1\text{H}, ^1\text{H})$ data for the analysis of the bonding situation in a cyclic π system was the detection of partial π -bond fixation in biphenylene (1),⁹ which in terms of resonance theory demonstrated the preference for Kekulé structures with exocyclic double bonds at the central four-membered ring. Later, the olefinic nature of tropone (2) was established from its $^3J(^1\text{H}, ^1\text{H})$ values,¹⁰ partial bond fixation in heterocyclic compounds was detected,^{11,12} and the characteristic $^3J(^1\text{H}, ^1\text{H})$ data measured for cyclic dienes and trienes were recognized as important tools for the structural analysis of cyclic diene–triene isomers like norcaradienes and cycloheptatrienes.¹³

(1)

(2)

A detailed investigation of the $^3J(^1\text{H}, ^1\text{H})_{\text{cis}}/R_{\mu\nu}$ and $P_{\mu\nu}$ relations in unsaturated six-membered rings of various

Figure 1 Dependence of $^3J(^1\text{H}, ^1\text{H})_{\text{cis}}$ on the CC bond length in the HC–CH fragment of six-membered rings [equation (1)]. (Reproduced with permission from H. Günther, ‘NMR Spectroscopy’, 2nd edn., Wiley, Chichester, 1995)

benzenoid aromatics and other hydrocarbons,^{14,15} where the magnitude of these constants ranges between 5 and 9 Hz (and—as for other $^3J(^1\text{H}, ^1\text{H})$ values—a positive sign is found¹⁶), finally led to equations (1) and (2) which can be used to derive bond length and π -bond order information from experimental $^3J(^1\text{H}, ^1\text{H})_{\text{cis}}$ data:

$$^3J(^1\text{H}, ^1\text{H})_{\text{cis}} = -351.0 R_{\mu\nu}(\text{nm}) + 56.65 \quad (1)$$

$$^3J(^1\text{H}, ^1\text{H})_{\text{cis}} = 12.47 P_{\mu\nu}(\text{HMO}) - 0.71 \quad (2)$$

The sensitivity of $^3J(^1\text{H}, ^1\text{H})_{\text{cis}}$ for bond length changes is high (Figure 1) and provides a valuable probe for the bonding situation in various cyclic π systems and annulenes. Steric compression and strain effects may cause deviations from equation (1) if changes of the HCC valence angles are induced.^{17,18} This becomes apparent if one compares the data for 1,4-di-*t*-butylnaphthalene¹⁸ with those of naphthalene¹⁵ or data for *o*-di-*t*-butylbenzene¹⁹ and the highly strained benzocyclopropene¹⁷ with those of the unstrained 9,10-dihydroanthracene¹⁷ (Figure 2).

Strain and steric compression are frequently encountered in fused ring systems where these factors cause a decrease in $^3J(1,2)$ and an increase in $^3J(2,3)$ if a small ring ($n < 6$) is fused to a large ring (3). The reverse trend—an increase of $^3J(1,2)$ and a decrease of $^3J(2,3)$ —is found if a larger ring is fused to a smaller one (4).²⁰

(3)

(4)

More drastic changes of the HCC valence angles are induced in π systems of different ring size and modified correlations have been derived for these cases:

Figure 2 The effect of steric compression and strain on $^3J(^1\text{H}, ^1\text{H})_{cis}$ values (in Hz) of various HC–CH fragments (a, b)

Table 1 The Ring Size Dependence of $^3J(^1\text{H}, ^1\text{H})_{cis}$ Values

Cycloalkene ring size	$^3J(\text{Hz})$
3 ²⁸	1.3
4 ²⁹	2.85
5 ²⁷	5.57
6 ²⁷	10.11
7 ²⁷	11.02
8 ²⁷	10.41

Five -membered rings:^{5,21}

$$^3J(^1\text{H}, ^1\text{H})_{cis} = -322.6R_{\mu\nu}(\text{nm}) + 48.45 \quad (3)$$

$$^3J(^1\text{H}, ^1\text{H})_{cis} = 7.12P_{\mu\nu}(\text{HMO}) - 1.18 \quad (4)$$

Seven-membered rings:^{20,22}

$$^3J(^1\text{H}, ^1\text{H})_{cis} = -367.4R_{\mu\nu}(\text{nm}) + 60.68 \quad (5)$$

$$^3J(^1\text{H}, ^1\text{H})_{cis} = 21.91P_{\mu\nu}(\text{HMO}) - 3.85 \quad (6)$$

The ring size dependence of the HCC valence angles is a consequence of the changes in internal CCC valence angles for the respective perimeters and a linear correlation of $\angle\text{CCC}$ with $^3J(^1\text{H}, ^1\text{H})_{cis}$ is thus not unexpected. Using five-, six-, seven-, and eight-membered ring systems, an increment of 0.29 Hz per degree was found after correcting for different π -bond orders.²³ Similar relations were established for the long-range $^1\text{H}, ^1\text{H}$ couplings 4J and 5J .²³ For isolated double bonds, the effect of HCC valence angle changes is most clearly seen by the ring size dependence of $^3J(^1\text{H}, ^1\text{H})_{cis}$ in cycloalkenes,^{24–27} as shown in Table 1.

A systematic study of $^3J(^1\text{H}, ^1\text{H})_{cis}$ for benzo-annelated annulenes³⁰ has shown that in addition to steric effects the electronic nature of the annulenes, i.e. the number of π electrons and the degree of delocalization, influences the $^3J(^1\text{H}, ^1\text{H})_{cis}$ data in the annelated benzene ring in a characteristic way. Thus, the π -electron structure of annulenes

can be monitored by the $^3J(^1\text{H}, ^1\text{H})_{cis}$ data for the benzene ring in the corresponding benzoannulene. The π -bond orders P_{12} and P_{23} are determined from the measured coupling constants according to equation (7), which is based on PPP–SCF π -electron calculations,^{31,32}

$$P_{\mu\nu}(\text{SCF}) = 0.104^3 J(^1\text{H}, ^1\text{H})_{cis} - 0.120 \quad (7)$$

a Q value being defined as $Q = P_{12}/P_{23}$. The magnitude of Q is related to the bonding situation in the annulene: $Q < 1.00$ for antiaromatic ($4n$) π systems, $Q > 1.10$ for aromatic ($4n + 2$) π systems, and $1.00 < Q < 1.10$ for olefinic systems. Typical examples are found with the benzotropylium ion (5)²³ and benzocycloheptatriene-id (6)³³ or the two dehydroannulenes (7) and (8).³⁴

Substituent effects have mostly been studied with substituted benzenes, where a careful determination of the $^3J(^1\text{H}, ^1\text{H})$ values³⁵ has established the effect of electronegativity: $^3J(\text{a,b})$ increases in the (X)C–CH_a–CH_b–CH_c–fragment if X is more electronegative than hydrogen, while a small decrease is found for the coupling $^3J(\text{b,c})$.

Vicinal $^1\text{H}, ^1\text{H}$ coupling via a *trans*-HC–CH fragment, $^3J(^1\text{H}, ^1\text{H})_{trans}$, is found only in larger annulene rings which tolerate *trans* double bonds. As a consequence of the different dihedral angle $\Phi = 180^\circ$, such couplings are larger than the *cis* values, as the data reported for [18]annulene [$^3J(^1\text{H}, ^1\text{H})_{cis} = 8.0$ and $^3J(^1\text{H}, ^1\text{H})_{trans} = 15.5$ Hz]³⁶ demonstrate. Other values have been collected in the literature,^{34,37} but a detailed analysis of these data was not attempted. For bridged annulenes, various steric requirements imposed on the perimeter geometry by the bridging group usually lead to a loss of coplanarity of all HC–CH fragments and the magnitude of the vicinal $^1\text{H}, ^1\text{H}$ coupling constants is subject to additional factors such as varying dihedral angles.^{38–40} Early theoretical calculations for $^3J(^1\text{H}, ^1\text{H})_{cis}$ have been reviewed.⁴¹

In conclusion, vicinal $^1\text{H}, ^1\text{H}$ coupling constants provide the basis for detailed insights into the electronic structure of annulenes and other cyclic π systems and complement the information obtained from shielding properties such as, for example, ring current effects.

1 INTRODUCTION

The term ‘amorphous’ describes a state of matter that possesses most of the macroscopic and thermodynamic properties of the solid state, while displaying the structural disorder and isotropic behavior typical of a liquid or gas. This lack of microscopic periodicity implies that it is not possible to describe the structure by a definite set of atomic coordinates and symmetry relations. Structural questions in amorphous systems concern distribution functions rather than fixed values of geometrical parameters. Furthermore, the structure can be influenced by the mode of preparation, thermal history, and by compositional variations. The following topics are of interest in the structural description of an amorphous solid: nearest-neighbor atomic connectivities (‘short-range order’); second and third-nearest neighbors and higher-order correlations (‘intermediate-range order’); topological disorder, i.e. the distribution of specific geometrical parameters; kinetic aspects, including the presence of restricted atomic or molecular motion below the glass transition temperature, T_g , and the motional processes associated with the glass transition; general thermodynamic and other macroscopic aspects, concerning the chemical equilibria and phase relationships involved, and the connection between glass structure and physical properties.

Techniques of solid state NMR are uniquely well suited for studying questions of this kind. Since NMR selectively probes the local environment of a chosen nuclear species, it easily lends itself to applications to disordered and compositionally complex systems. The direct proportionality of the signal intensity to the number of nuclei makes NMR the method of choice for quantitative applications in the bulk. The structural information arises from terms in the spin Hamiltonian that describe the internal interactions of the magnetic nuclei with their electronic and magnetic local environments. These terms, which are incorporated in the theoretical treatment by means of standard perturbation theory, are: direct (through-space) nuclear dipole–dipole coupling, $\hat{H}_d$, indirect nuclear spin–spin coupling, $\hat{H}_J$, chemical shielding, $\hat{H}_{CS}$, and, for nuclei with spin quantum numbers $> \frac{1}{2}$, nuclear electric quadrupole coupling, $\hat{H}_Q$. All of the internal interactions are anisotropic, and $\hat{H}_J$ and $\hat{H}_{CS}$ also contain an isotropic part. Furthermore, $\hat{H}_d$ and $\hat{H}_J$ have

homonuclear and heteronuclear contributions with intrinsically different transformation properties.

The NMR spectroscopist addressing structural questions in solids thus faces a dual task: (i) to evaluate accurately the parameters (and their distribution functions) characterizing the Hamiltonians of these internal interactions, and (ii) to uncover the structural significance of the numerical values or distribution functions thus obtained.

The most successful strategy for meeting the first task is to simplify the effective spin Hamiltonian by ‘selective averaging’ experiments. A combination of several such experiments often results in a wealth of complementary information. The second task involves finding a physical relationship between an interaction parameter and local geometries. In the case of $\hat{H}_d$ there is a straightforward dependence on internuclear distances. In the case of other interactions one often takes recourse to empirical correlations established with crystalline model compounds or ab initio calculations on simple molecular models mimicking the nearest-neighbor environments. In systems where the composition is variable, the detailed dependence of chemical shifts or quadrupolar couplings on the composition of the material offers important structural insights. On occasion, structural information on an amorphous material has also been inferred from the detailed temperature dependence of the NMR chemical shifts in the liquid state.

Overall there are well over 3000 publications dealing with NMR studies of amorphous materials, more than 1000 of which deal with the structure of inorganic systems. Since space limitations preclude a comprehensive treatise of this work, the present review will focus on the work deemed most influential, representative, and/or best exemplifying the potential of solid state NMR in glass science. These choices are certainly based on the highly subjective tastes of the author, who wishes to apologize in advance for omitting any important work that should have been cited.

2 HISTORICAL BACKGROUND

NMR measurements on glasses began to appear in the 1950s;¹ however, the CW NMR study of ^{11}B in borate glasses in 1958 by Silver and Bray was really the first one to provide any insight into glass structure.² Borate glasses contain variable amounts of three- and four-coordinate boron sites, which are easily discriminated by low-field CW NMR, because of their large difference in the magnitude of the nuclear electric quadrupolar coupling constant. While the exploration of borate glasses using low-field CW NMR (and more recently NQR) techniques continues to the present date, such studies of other nuclei were generally plagued by low detection sensitivities, saturation effects, and limited chemical shift dispersion due to the use of low field strengths.

The nearly simultaneous publication in 1982 of several pulsed, high-field Fourier transform NMR studies,^{3–6} using line narrowing by MAS constituted a major breakthrough. This technique made it possible to resolve (and thereby quantify) distinct local structures present in silicate glasses and to provide unambiguous information about the coordination number of aluminum and other important glass constituents. Although MAS has remained the mainstay of NMR applications to amorphous materials to the present date, during the past decade

new third-generation experiments have emerged, whose applications to glasses have recently produced insights of amazing detail. Many of these newer techniques utilize the inherent advantages of multifrequency irradiation and multidimensional data processing, providing correlation and enhanced resolution, and quantitative specification in more than one interaction domain.

Several recent reviews have been given on the subject of NMR of amorphous materials.^{7–10} While these articles are by now slightly out of date due to the rapid development of this field, they are still valuable sources of information, because in the field of glass science the use of improved NMR technology has only rarely resulted in a major reevaluation of previous work and/or dramatic changes in the mode of thinking. More commonly, the progress over the years has been the resolution of more and more detail, in many cases reinforcing and providing new rationales to earlier interpretations.

3 SILICATE GLASSES

The majority of modern NMR studies conducted on amorphous materials during the past 10 years has been in the area of silicate glasses. The great interest in these systems arises from their importance as structural and optical materials, and from the pivotal role of molten silicates in the earth sciences. Figure 1 summarizes the principal questions studied in this area. Specifically, the NMR studies have been devoted to (i) the Si–O–Si bond angle distribution, (ii) the distribution of nonbridging oxygen atoms introduced by network modifiers, (iii) the spatial distribution of alkali and alkaline earth metal cations, (iv) the structural role and the distribution of intermediate oxides such as Al_2O_3 , (v) anion

Figure 1 Structural and chemical issues in the area of silicate glasses studied by ^{29}Si NMR spectroscopy. A, network modification by alkali ions; B, glass synthesis by the sol-gel method; C, hydrolysis; D, coordination change at high pressures; E, F, G, nearest-neighbor substitution with fluorine, nitrogen, and carbon; H, next-nearest neighbor substitution by alumina and other network-forming oxides (Reproduced by permission of Pergamon Press from H. Eckert, *Prog. Nucl. Magn. Reson.*, 1992, **24**, 159)

substitution effects (F, C, N), (vi) the speciation and structural role of water and other volatiles, (vii) the effect of high pressures, and (viii) the influence of sol-gel processing upon the structure of these glasses.

3.1 Bond Angle Distribution in Vitreous SiO_2 and Alkali Silicate Glasses

While glassy silica retains the local structure based on corner-shared $\text{SiO}_4/2$ tetrahedra present in all of the ambient-pressure polymorphs of silica, the intrinsic disorder in this material is attributed to a large variability in the Si–O–Si bond angle. This view is supported by theoretical calculations, which show a very broad energy minimum in the Si–O–Si bond angle distribution $F_\alpha(\text{Si–O–Si})$.¹¹ In principle, this distribution function can be probed by NMR, because ^{29}Si chemical shifts are correlated empirically with the mean Si–O–Si bond angle. A variety of physical correlations have been proposed, and have been critically reviewed and compared with each other in the literature.^{12,13}

The ^{29}Si MAS NMR spectrum of vitreous silica has an approximately Gaussian shape centered at -112 ppm with a full width at halfheight of 11.5 ppm .¹⁴ Under the usual MAS conditions ($3\text{--}5\text{ kHz}$) in samples containing ^{29}Si at natural abundance, the lineshape is entirely governed by a distribution of isotropic chemical shifts. Thus, using one of the correlations proposed, Si–O–Si bond angle distribution functions can be inferred. The results (Figure 2) suggest a most probable Si–O–Si bond angle of between 142° and 151° (depending on which empirical correlation is used) and a narrower distribution function than deduced from X-ray diffraction.

A fundamental difficulty of this procedure arises from the fact that the measured chemical shift reflects the composite effect of four Si–O–Si bond angles. This difficulty has been overcome by ^{17}O NMR studies of the bridging oxygen sites. Ab initio calculations carried out on the model molecule $\text{H}_3\text{Si–O–SiH}_3$ have shown that the ^{17}O nuclear electric quadrupolar coupling parameters χ and η depend on the intertetrahedral bond angles α .¹⁵ Indeed, these calculations reflect the same trend as predicted by a simple oxygen sp hybridization model:

Figure 2 Various Si–O–Si bond angle distribution functions derived from ^{29}Si chemical shift data, using four different empirical correlations. Details are discussed elsewhere^{12,13} (Reproduced by permission of Elsevier Science Publishers BV from R. F. Pettifer, R. Dupree, I. Farnan, and U. Sternberg, *J. Noncryst. Solids*, 1988, **106**, 408)

$$\chi \sim \cos \alpha / (1 - \cos \alpha) \quad (1)$$

$$\eta = 1 + \cos \alpha \quad (2)$$

Thus, with increasing α values, χ increases, whereas η decreases, approaching the value of zero for the cylindrically symmetric environment when $\alpha = 180^\circ$. These correlations have been qualitatively confirmed by experimental ^{17}O NMR measurements on model compounds. Obtaining a distribution of Si–O–Si bond angles α then requires that the distribution functions of χ and/or η be determined in an accurate fashion. Farnan et al. have accomplished this feat for glassy $\text{K}_2\text{Si}_4\text{O}_9$, using 2D DAS NMR.¹⁶ The experiment yields a completely isotropic spectrum in the projection on the ω_1 axis, correlated with lineshapes perturbed by the electric field gradient in the anisotropic ω_2 dimension. Figure 3 reveals a systematic variation of the magnitude and asymmetry of the electric field gradient across the isotropic lineshape in the ω_1 domain: progressing from low to high values of ω_1 , χ decreases while η increases, in good agreement with the predictions made by eqs. (1) and (2). The distribution function of α derived on the basis of this 2D correlation is shown as the solid circles in Figure 4(c). This analysis can be extended further to derive a more complete distribution function (open circles in Figure 5) if the entire lineshape in the ω_1 domain is transformed into the distribution of ^{17}O second-order nuclear electric quadrupolar shifts. Characteristically, the bond angle distribution is significantly narrower than that obtained by X-ray diffraction on glassy silica.¹⁷ It is also

Figure 3 Oxygen-17 DAS NMR results on glassy $\text{K}_2\text{Si}_4\text{O}_9$. Indicated are the individual anisotropic slices for various points across the broadened DAS spectrum in the isotropic dimension. Note the systematic change in the asymmetry parameter. 3.2 Network Structure of Silicate Glasses

3.2.1 Analysis of $\text{Si}^{(n)}$ Sites by ^{29}Si NMR.

Incorporation of alkali and alkaline earth oxides into glassy silica leads to depolymerization with formation of nonbridging oxygen atoms. As a result, silicate glasses generally contain the five distinct silicon microstructures ($\text{Si}^{(n)}$) species (also labeled $\text{Q}^{(n)}$ species in the literature) shown in Figure 7. Benchmark data on crystalline model compounds reveal that each type of $\text{Si}^{(n)}$ unit is distinguished by a unique isotropic ^{29}Si chemical shift range,¹⁹ and chemical shift anisotropy powder pattern: specifically, the isotropic environments of $\text{Si}^{(4)}$ and $\text{Si}^{(0)}$ species result in sharp static ^{29}Si NMR spectra, which are easily distinguished from the anisotropically broadened $\text{Si}^{(1)}$,

Figure 7 $\text{Si}^{(n)}$ (also labeled $\text{Q}^{(n)}$ in the literature) species in alkali silicate glasses and their ^{29}Si chemical shift powder patterns (Reproduced by permission of Pergamon Press from H. Eckert, *Prog. Nucl. Magn. Reson.*, 1992, **24**, 159)

$\text{Si}^{(2)}$, and $\text{Si}^{(3)}$ resonances. Furthermore, the latter three species differ in the sign of the anisotropy and in the asymmetry of the shielding tensor.

The MAS NMR spectra of ^{29}Si in alkali silicate glasses yield partially resolved resonances for the various $\text{Si}^{(n)}$ species, which are usually deconvoluted into Gaussians [Figure 8(a)]. In most cases, the $\text{Si}^{(n)}$ species distributions thus obtained are quantitatively compatible with the amount of nonbridging oxygen introduced with the network modifier.²⁰ Small concentrations of $\text{Si}^{(4)}$ and $\text{Si}^{(0)}$ are most favorably detected by static NMR.²¹

3.2.2 $\text{Si}^{(n)}$ Species Distribution in Binary Silicate Glasses

The quantitative distribution of $\text{Si}^{(n)}$ units in alkali silicate glasses has been discussed in terms of two possible schemes: in the ‘binary’ model the glass structure contains only those $\text{Si}^{(n)}$ species that are present in the bordering stoichiometric crystalline phases, while in the statistical model all sites are present, their contributions calculable from binomial statistics.

Figure 8 (a) Compositional dependence of the ^{29}Si MAS NMR spectra in the glass system $\text{Na}_2\text{O}-\text{SiO}_2$. Peak assignments are indicated. (Reproduced with permission of The Society of Glass Technology and Elsevier Science Publishers BV from H. Maekawa, T. Maekawa, K. Kawamura, and T. Yokokawa, *J. Noncryst. Solids*, 1991, **127**, 53). (b) Quantitative predictions for the ^{29}Si species distributions in the binary and the random model. $\blacktriangle$, $Q^{(0)}$; $\square$, $Q^{(1)}$; $\triangle$, $Q^{(2)}$; $\times$, $Q^{(3)}$; $\bullet$, $Q^{(4)}$. (Reproduced with permission of The Society of Glass Technology and Elsevier Science Publishers BV from R. Dupree, N. Ford, and D. Holland, *Phys. Chem. Glasses*, 1987, **28**, 78)

Figure 8(b) contrasts the quantitative predictions made by the two different models. The experimental results reported in more recent studies²⁰ in most cases detect clear deviations from the binary distribution; however, the $\text{Si}^{(n)}$ distribution is

far from random. This intermediate situation can be modeled by assuming melt equilibria of the kind²²

characterized by equilibrium constants K_3 , K_2 , and K_1 , respectively. $K_i = 0$ corresponds to the binary model, $K_i = 1$ to the random situation, and $K_i \gg 1$ to phase segregation and/or crystallization. K_i tends to increase with increasing ionic potential Z/r of the cation in the glass. Thus, lithium silicate glasses show the highest tendency toward site randomization, whereas in potassium silicate glasses K_i is so small that the distribution approaches that predicted by the binary model.²³ Furthermore, in general $K_1 > K_2 > K_3$. The effect of the alkali ions upon the silicon site distribution may reflect changes in the electronic properties of the Si–O bonds, as suggested by recent ab initio MO calculations.²⁴

The relevant temperature for these equilibrium constants K_i is the glass transition temperature T_g , at which all bond-breaking and bond-making processes are frozen in. By varying T_g over a range of 80 K (using different quenching rates), Brandriss and Stebbins showed that for $\text{Na}_2\text{Si}_2\text{O}_5$ glass, K_1 for the reaction (3a) increases with increasing temperature. From this temperature dependence, ΔH is estimated at $30 \pm 15 \text{ kJ mol}^{-1}$.²⁵ Similar effects are observed in a mixed $\text{Na}_2\text{O}-\text{CaO}$ -silicate glass.

3.2.3 Spatial Distribution and Intermediate Range Order

As known from the structure of metasilicates and other crystalline model compounds, nonbridging oxygen atoms tend to aggregate around modifier cations and vice versa, resulting in a cation distribution that resembles clustering at least at low modifier concentrations. The cation distribution is closely linked with the spatial distribution of the various $\text{Si}^{(n)}$ units. Are they statistically linked within a single extended network or do they form separated islands? Direct evidence for $\text{Si}^{(n)}-\text{O}-\text{Si}^{(n-1)}$ connectivity has come from 2D COSY-MAS NMR studies (Figure 9) on two ^{29}Si -enriched sodium silicate glasses with Na_2O contents of 20 and 41 mol%, respectively.²⁶ The cross peaks seen in Figure 9 between the $\text{Si}^{(3)}$ and $\text{Si}^{(4)}$ resonances arise from coherence transfer via two-bond scalar coupling, thus providing direct evidence for such links. Participation in a $\text{Si}^{(n)}-\text{O}-\text{Si}^{(n-1)}$ linkage appears to shift the $\text{Si}^{(n)}$ resonance to lower frequency and the $\text{Si}^{(n-1)}$ resonance to higher frequency compared with respective majority sites. This finding probably signifies bond angle redistributions that may be unique to such site connections. The results thus support the description of these glasses as continuous networks, although the 2D experiments indicate only that such links exist in principle; their exact quantification requires further work.

3.2.4 Si^n Species Distribution in Alkaline Earth Silicate Glasses and Related Systems

Silicon-29 MAS NMR spectra of silicate glasses modified by divalent cations show no clear site resolution, indicating that the spread of chemical shifts due to bond angle variations is comparable to the effect of the nonbridging oxygen.²⁷

Figure 9 2D ^{29}Si COSY of a glass with the composition $\text{Na}_2\text{Si}_4\text{O}_9$. The $\text{Si}^{(3)}\text{--Si}^{(4)}$ connectivities are revealed by the cross peaks b and a. (Reproduced with permission of Elsevier Science Publishers BV from C. T. G. Knight, R. J. Kirkpatrick, and E. Oldfield, *J. Noncryst. Solids*, 1990, **116**, 140)

Significantly better resolution is observed in the system PbO--SiO_2 . Here, the statistical $\text{Si}^{(n)}$ distribution seems to be favored,²⁸ in sharp contrast to alkali silicate glasses. Pb_2SiO_4 glass (66.6 mol% PbO) appears to be an interesting example where the $\text{Si}^{(n)}$ speciation differs from that expected from the composition.²⁹ Several crystalline Pb_2SiO_4 polymorphs are known, none of which has $\text{Si}^{(0)}$ sites, in spite of the orthosilicate stoichiometry. The structure of the glass resembles that of the low-temperature polymorph, which contains dimeric $\text{Si}^{(1)}$ environments. This, in turn, implies that the glass must contain Pb--O--Pb bonds, a view indeed supported by some very early ^{207}Pb NMR work.³⁰

3.3 Aluminosilicate Glasses

3.3.1 General Aspects and Spectroscopic Approaches

Introduction of Al_2O_3 into alkali silicate glasses enhances their thermal, mechanical, and chemical stability to a considerable extent, resulting in widespread practical applications. Structural questions associated with these effects include (i) the influence of aluminum on the $\text{Si}^{(n)}$ distribution, (ii) the distribution of Si--O--Si and Si--O--Al linkages, and (iii) the coordination number of aluminum and its structural role in the network. The spectroscopic approaches to these questions have been largely traditional, namely ^{29}Si MAS NMR (which is of limited benefit) and ^{27}Al MAS NMR, which affords a straightforward assignment of aluminum coordination number.

The structure of aluminosilicate glasses can be discussed in terms of 15 different $\text{Si}_m^{(n)}$ units, corresponding to SiO_4 tetrahedra with all possible permutations of n bridging oxygen atoms and m aluminum next-nearest neighbors ($m \leq n$). Studies of crystalline model compounds show that the presence

Figure 10 Wideline ^{29}Si NMR in aluminosilicate glasses along the compositional series $(1-x)\text{Na}_2\text{O} \cdot x\text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2$. Note the emergence of an $\text{Si}^{(3)}$ powder pattern (chemical shift principal components indicated by arrows) at low Al/Na ratios. (Reproduced with permission of The American Chemical Society from H. Maekawa, T. Maekawa, K. Kawamura, and T. Yokokawa, *J. Phys. Chem.*, 1991, **95**, 6822)

of aluminum next-nearest neighbors has a strong effect on δ_{iso} (^{29}Si). Unfortunately, however, changes in m as well as in n by one unit lead to chemical shift effects of comparable magnitude, generally resulting in poorly resolved spectra whose interpretation is highly ambiguous. In contrast, ^{27}Al MAS NMR offers a fairly easy distinction in chemical shift between four-coordinate aluminum (Al^{IV} , $40 \text{ ppm} \leq \delta_{\text{iso}} \leq 80 \text{ ppm}$), five-coordinate aluminum (Al^{V} , $20 \text{ ppm} \leq \delta \leq 40 \text{ ppm}$), and six-coordinate aluminum (Al^{VI} , $-20 \text{ ppm} \leq \delta_{\text{iso}} \leq 20 \text{ ppm}$). Quantitative interpretations are often complicated by signal loss due to second-order quadrupolar broadening effects, and careful spin-counting studies on weighed samples are mandatory.

The structures of alkali or alkaline earth silicate glasses (general formula $\text{M}_{(2)}\text{O--Al}_2\text{O}_3\text{--SiO}_2$) depend critically on the Si/Al and the M/Al molar ratios, and show common features within each of the following four groups:

- Region A: $\text{Al}_2\text{O}_3/\text{SiO}_2 \leq 0.5$ and $\text{M}_{(2)}\text{O}/\text{Al}_2\text{O}_3 = 1$.
- Region B: $\text{Al}_2\text{O}_3/\text{SiO}_2 \leq 0.5$ and $\text{M}_{(2)}\text{O}/\text{Al}_2\text{O}_3 > 1$.
- Region C: $\text{Al}_2\text{O}_3/\text{SiO}_2 > 0.5$ and $\text{M}_{(2)}\text{O}/\text{Al}_2\text{O}_3 \geq 1$.
- Region D: $\text{M}_{(2)}\text{O}/\text{Al}_2\text{O}_3 < 1$.

3.3.2 Region A: Fully Polymerized Aluminosilicate Networks

Most ^{29}Si and ^{27}Al MAS NMR studies have supported the preexisting view that such glasses are fully polymerized networks comprised of $\text{Si}^{(4)}$ units and MAIO_2 fragments

($\text{AlO}_{4/2}^-$ tetrahedra balanced by cationic charges).^{7,31,32} The ^{29}Si MAS NMR spectra of such glasses are poorly resolved and the center of gravity is shifted to higher frequency, from -110 to -86 ppm with an increasing ratio of $\text{Al}_2\text{O}_3/\text{SiO}_2$, reflecting the successive replacement of Si–O–Si bonds by Si–O–Al linkages. Similar trends in chemical shifts have been observed experimentally in zeolites. All of these results are consistent with the Lowenstein rule,³³ according to which $\text{Al}^{\text{IV}}\text{–O–Al}^{\text{IV}}$ linkages, which represent an energetically unfavorable accumulation of charge in the network, are being avoided.

Recently, unusual behavior was found in rapidly quenched slightly peraluminous samples along the $\text{MgAl}_2\text{O}_4\text{–SiO}_2$ join, indicating substantial amounts of five- and six-coordinate aluminum atoms.³⁴ This result requires further examination.

3.3.3 Region B: Modified Aluminosilicate Networks

These glass compositions have excess modifier oxide, which in principle could create nonbridging oxygen atoms coordinated with either the silicon or the aluminum sites. Wide-line NMR studies of the system $4\text{SiO}_2\text{–}(\text{Na}_2\text{O})_{1-x}\text{–}(\text{Al}_2\text{O}_3)_x$ ($0 \leq x \leq 0.5$) strongly favor the former possibility. Figure 10 shows that as the Al/Na ratio is decreased from 0.5 to 0.1, the axially symmetric chemical shift pattern of $\text{Si}^{(3)}$ units (not bonded to aluminum) emerges with its quantitatively expected contribution.³⁵ Figure 11 shows the number of nonbridging oxygen atoms per tetrahedral atom (obtained by NMR peak area analysis) as a function of $N_{\text{Al}} = 4[\text{Al}]/([\text{Al}] + [\text{Si}])$ in this glass system. These data are compared with (i) a model assuming that the excess sodium oxide modifies the Si–O–Si bonds excessively (solid lines) and (ii) a model assuming random association of Na_2O with nonbridging oxygen atoms attached to both silicon and aluminum atoms. Clearly the data favor model (i), revealing that the nonbridging oxygen atoms are directed towards the silicon atoms.³⁵ This result is expected, since attachment of a nonbridging oxygen to a negatively charged AlO_4^- unit is electrostatically less favorable than its attachment to an uncharged silicon unit.

3.3.4 Region C: Alumina-Rich Charge-Balanced Aluminosilicate Glasses

The region of glass formation in the system $\text{CaO–Al}_2\text{O}_3\text{–SiO}_2$ extends all the way to glassy CaAl_2O_4 . This material is of interest for applications to long-wavelength optical fibers. The aluminum atoms are tetrahedrally coordinated as found in crystalline CaAl_2O_4 . The corresponding magnesium compound has six-coordinated aluminum atoms and is impossible to vitrify. Ultrahigh-temperature NMR studies reveal a large chemical shift difference between both liquids, indicating differences in the average coordination numbers.³⁶ Addition of small amounts of SiO_2 to molten CaAl_2O_4 results in glasses that are more stable toward recrystallization. The ^{29}Si chemical shifts in these silica-poor glasses lie between -75 and -78 ppm, consistent with either $\text{Si}^{(4)}(\text{OAl})_{4/2}$ units or with depolymerized $\text{Si}^{(2)}$ groups.³⁷ If part of the CaO were indeed used to generate nonbridging oxygen atoms associated with $\text{Si}^{(2)}$, not enough CaO would be available to charge balance the AlO_4^- groups, and thus aluminum in higher coordination numbers should be observed. NMR results for sodium and calcium

Figure 11 Numbers of nonbridging oxygen atoms per tetrahedral atom (aluminum and silicon) obtained from NMR peak area analysis (circles) in sodium aluminosilicate glasses. Solid line: calculated number assuming that nonbridging oxygen atoms are exclusively associated with silicon atoms. Dashed line: calculated number assuming that nonbridging oxygen atoms are associated with both silicon and aluminum atoms. (Reproduced with permission of The American Chemical Society from H. Maekawa, T. Maekawa, K. Kawamura, and T. Yokokawa, *J. Phys. Chem.*, 1991, **95**, 6822)

aluminosilicate glasses are contradictory with regard to this question; particularly concerning the structure of $\text{CaAl}_2\text{SiO}_6$ glass.^{38,39}

3.3.5 Region D: Peraluminous Aluminosilicate Glasses

Aluminosilicate glasses in which the $\text{M}_{(2)}\text{O}/\text{Al}_2\text{O}_3$ ratio is below 1, lack the cations necessary to balance the negative charge associated with the Al^{IV} sites. Consequently, not all of the aluminum atoms can be present in this form. Considerations of this kind have led to the proposal of charge-neutral $\text{Al}(\text{AlO}_2)_3$ ‘triclusters’;⁴⁰ other possibilities include extended phase segregation, or a network-modifier role of the aluminum atoms. In general support with such proposals, ^{27}Al NMR studies reveal that in all peraluminous glasses a significant fraction of the aluminum atoms are five- and six-coordinate.^{31,38} Typical results are shown in Figure 12. On the other hand, the NMR data are not sufficiently informative to advocate specific structural proposals for these glasses.

3.3.6 Binary $\text{SiO}_2\text{–Al}_2\text{O}_3$ Glasses

The binary system $\text{SiO}_2\text{–Al}_2\text{O}_3$ shows a region of metastable liquid–liquid immiscibility, resulting in glasses whose structures show a strong dependence on quenching

Figure 12 Typical ^{27}Al MAS NMR spectra of various calcium aluminosilicate glasses. The numerals indicate the molar ratios of $\text{CaO}:\text{Al}_2\text{O}_3:\text{SiO}_2$. (Reproduced with permission of The Society of Glass Technology and Elsevier Science Publishers BV from G. Engelhard, M. Nofz, K. Forkel, F. G. Wihsmann, M. Magi, A. Samoson, and E. Lippmaa, *Phys. Chem. Glasses*, 1985, **26**, 157)

rate. Apparently homogeneous glasses, obtained either by “superquenching” (rates of $10^5\text{ }^\circ\text{C s}^{-1}$) or by sol–gel technology show aluminum to be present in four, five, and six-fold coordination, whereas for the phase-separated glasses the NMR spectra reveal primarily Al^{IV} and Al^{VI} . Spin-counting studies and comparison with reference standards reveal further that in the superquenched samples only $\sim 70\text{--}85\%$ of aluminum atoms are observable, whereas in slower quenched samples the detection is quantitative.⁴¹ There are also large differences in the ^{29}Si NMR spectra: in the phase-separated samples the silicon environments resemble those in glassy SiO_2 , whereas in the superquenched samples, signal contributions at higher frequencies indicate either nonbridging oxygen

Figure 13 A structural motif of amorphous silica-aluminas with a low-to-moderate aluminum content

atoms or Si-O-Al connectivities.⁴¹ Apparently the ordering that accompanies the unmixing of the two liquid phases disfavors the formation of Al^{V} and possibly of other highly distorted sites.

3.3.7 Amorphous Silica-Aluminas

Amorphous silica-aluminas are high surface area materials that can be prepared by coprecipitation or sol–gel techniques from solutions containing sodium silicate and sodium aluminate. Owing to their high surface acidities they are potent hydrocarbon-cracking catalysts, but their activity is strongly dependent on the silica/alumina ratio and on the method of preparation. It is possible to generate both single-phase and diphasic materials. Diphasic materials are prepared by mixing sols of silica and boehmite, and studies by MAS NMR of ^{27}Al and ^{29}Si confirm that the resulting powders can be viewed as intimate mixtures of amorphous silica and γ -alumina. In contrast, preparation from solutions containing both sodium silicate and sodium aluminate results in monophasic materials over a wide compositional region. For low-to-moderate aluminum contents, aluminum is thought to substitute into the silica network. Protons balance the resulting negative charge on the network, giving rise to sites of the type shown in Figure 13 which possess high Brønsted acidities. Charge balancing is also accomplished by partially hydrolyzed Al^{3+} cations in octahedral environments, and phase separation occurs for $\text{Al}/(\text{Al} + \text{Si})$ ratios above 0.8, with the formation of crystalline γ -alumina.⁴² In general, ^{27}Al MAS NMR spectra show that the fraction of Al^{VI} sites can be highly variable, but increases with increasing $\text{Al}/(\text{Al} + \text{Si})$ ratio. In samples with high alumina contents the signal is indistinguishable from that of γ -alumina. The spectra are also greatly affected by the state of hydration⁴³ and by the details of sample preparation.

3.4 Anion Substitution in Silicate Glasses

Partial replacement of oxide by fluoride, nitride, or carbide ions influences both the optical and mechanical properties of silicate glasses. NMR studies have helped understand these features on a structural basis. Duncan et al. have studied the atomic distribution of small amounts of fluoride in glassy silica.⁴⁴ In principle, the incorporation of fluorine could generate $\text{SiO}_3/2\text{F}$, $\text{SiO}_2/2\text{F}_2$, $\text{SiO}_{1/2}\text{F}_3$, and SiF_4 coordination environments, which are easily distinguishable on the basis of the homonuclear $^{19}\text{F}\text{--}^{19}\text{F}$ dipolar coupling. Spin echo spectroscopy of a glass containing 1.03 wt.% fluorine reveals that only the first two units are present. The $\text{SiO}_2/2\text{F}_2$ units, which contain two closely spaced fluorine atoms, are responsible for a fast-decaying component at short evolution times ($2t_1 < 0.2\text{ ms}$), whereas the less strongly coupled fluorine atoms in the $\text{SiO}_3/2\text{F}$ units give rise to a much slower spin echo decay component at longer evolution times.

Comparison of the experimental data with simulations reveals that the fraction of $\text{SiO}_{2/2}\text{F}_2$ units is substantially enhanced over the statistical probability.

Fluorine containing aluminosilicate glasses are important model systems for geological glasses, since fluorine is a frequent volatile component in natural magmas. Similarly to water, the presence of fluorine reduces the melt viscosity and increases the diffusion coefficients, even at small concentrations. The location of the fluorine species in geologically relevant aluminosilicate glasses has been addressed recently by multinuclear MAS MR.^{45,46} Cross polarization from ^{19}F dramatically enhances the spectral contribution from five- and six-coordinate aluminum sites,⁴⁵ hence suggesting that fluorine preferentially coordinates with aluminum. In support of this conclusion, $^{19}\text{F} \rightarrow ^{29}\text{Si}$ CP MAS experiments give no evidence for Si–F bonds.⁴⁶ The effect of fluoride on the melt viscosity is attributed to a depolymerization process resulting in the formation of AlF_5^{2-} and AlF_6^{3-} species. Ab initio calculations of the ^{27}Al nuclear electric quadrupolar coupling constants suggest that the five-coordinate species are actually $\text{AlF}_3(\text{OH})_2$ sites with D_{3h} symmetry.⁴⁷

In silicon oxynitride glasses, Si–O bonds are partially substituted by Si–N bonds, resulting in a more rigid network due to an increased average coordination number. Compared with regular $\text{Si}^{(4)}$ sites, nitrogen-bonded $\text{Si}^{(4)}$ -type species resonate at higher frequencies, and NMR chemical shift analysis can be used to estimate the average number of Si–N bonds. In nitrated aluminosilicate glasses, nitrogen shows a distinct preference for silicon over aluminum.⁴⁸ Amorphous oxycarbide materials can be realized from sol–gel chemistry, followed by pyrolysis. These materials contain mixed $\text{SiO}_{4-n}\text{C}_n$ local environments, which are well resolved by ^{29}Si MAS NMR.⁴⁹

3.5 Silicate Glass and Melt Structure at High Temperatures and Pressures

An important feature of glassy materials as contrasted to other crystalline or amorphous solids is the phenomenon of structural relaxation, associated with long-range molecular mobility activated above the glass transition temperature T_g . NMR spectroscopy affords techniques for the study of glass and melt dynamics over a wide range of timescales. Very slow atomic motions (timescale ~ 1 s) are sensitively detected by 1D or 2D chemical shift exchange spectroscopy. NMR lineshape parameters are affected by motions with correlation times in the millisecond region, whereas the spin–lattice relaxation times are most sensitive to motions on the timescale of nuclear precession periods, i.e. 10^{-8} s.

High-temperature studies of silicate glasses reveal an essentially rigid structure on the NMR timescale at temperatures below T_g . 2D ^{29}Si chemical exchange spectroscopy has shown that in glassy $\text{K}_2\text{Si}_4\text{O}_9$ the glass transition at 500°C is probably associated with a slow $\text{Si}^{(4)} \rightarrow \text{Si}^{(3)}$ site exchange process.⁵⁰ Figure 14 shows a typical result, obtained at 571°C . Site exchange manifests itself as a cross peak (-106 ppm, -55 ppm) corresponding to the peak maxima of the static powder patterns of $\text{Si}^{(4)}$ and $\text{Si}^{(3)}$, respectively. $\text{Si}^{(4)} \rightarrow \text{Si}^{(3)}$ site exchange is very slow at this temperature, and thus has no effect on the static NMR lineshapes. Nevertheless, these results establish a direct link between the glass transition

Figure 14 Contour plot of the 2D chemical exchange ^{29}Si NMR spectrum of $\text{K}_2\text{Si}_4\text{O}_9$ glass at 571°C . The cross peaks C and D reveal that the $\text{Si}^{(3)}$ and $\text{Si}^{(4)}$ species are in chemical exchange. Feature E possibly reflects a five-coordinated species in equilibrium with $\text{Si}^{(4)}$. (Reproduced with permission of Elsevier Science Publishers BV from I. Farnan and J. F. Stebbins, *J. Noncryst. Solids*, 1990, **124**, 207)

and the Si–O bond-breaking/bond-making processes resulting in chemical exchange phenomena, and explain why fibers quenched during rapid shearing of liquids produce no local alignment.⁵¹ Since the Si–O bonds are so labile at temperatures as low as T_g , shearing cannot produce cooperative flow.

Figure 15 shows that the $\text{Si}^{(3)}$ and $\text{Si}^{(4)}$ powder patterns persist up to temperatures of 700°C , $\sim 200^\circ\text{C}$ above T_g , before being affected simultaneously by site exchange and motional narrowing. Above 1000°C , the fast exchange limit is reached, and sharp ‘liquid-like’ spectra are observed. Although rather complex, it is possible to simulate the chemical exchange effect on the lineshape, and derive approximate exchange rates at different temperatures (Figure 15).⁵² The Arrhenius plot of exchange rate versus temperature yields an activation energy of $179.4 \pm 5.4 \text{ kJ mol}^{-1}$. Furthermore, from back-extrapolation of this line it is predicted that the exchange rate at T_g amounts to $\sim 9 \text{ Hz}$.⁵² Because of the availability of empty d orbitals on the silicon atom, it is reasonable to speculate that the site interchange mechanism is based on an addition/elimination mechanism, involving a higher-coordinate silicon intermediate. Indeed, the ^{29}Si silicon NMR spectra of various $\text{M}_2\text{Si}_4\text{O}_9$ glasses show a weak peak (comprising ~ 0.06 – 0.10% of the total ^{29}Si signal) around -150 ppm.^{53,54} This chemical shift appears approximately halfway between those measured for four- and six-coordinate silicon sites and is therefore assigned to five-coordinate silicon atoms (Si^{V}). Substantial amounts of Si^{V} and Si^{VI} are present in analogous $\text{Na}_2\text{Si}_4\text{O}_9$ glasses quenched from elevated pressures ($>6 \text{ GPa}$), hence further supporting the above peak assignment (Figure 16).⁵⁵ The structural behavior of silicate melts at high pressures is of central importance for the understanding of many geological processes occurring in the Earth’s interior. The

Figure 15 (a)–(e) Variable-temperature ^{29}Si NMR spectra of $\text{K}_2\text{Si}_4\text{O}_9$ glass and (f)–(j) corresponding simulations based on chemical exchange between $\text{Si}^{(3)}$ and $\text{Si}^{(4)}$ units. Temperatures and exchange rates are: (a) 697°C , (b) 774°C , (c) 800°C , (d) 847°C , (e) 997°C , (f) 2000 Hz, (g) 10 000 Hz, (h) 25 000 Hz, (i) 50 000 Hz, (j) 500 000 Hz. gradual change in silicon coordination number is illustrated in Figure 16 for $\text{Na}_2\text{Si}_4\text{O}_9$ glasses quenched at different external pressures and decompressed at room temperature. In contrast, no coordination change appears for albite melts in a similar pressure range.⁵⁶

3.6 The Interaction of Water with Silicate Melts and Glasses

Silicate melts are known to dissolve considerable amounts of water at elevated temperatures and pressure, resulting in dramatic effects on the physical and optical properties of the glasses. From a structural point of view, water is thought to depolymerize the silicate network, according to the reaction

Figure 16 Silicon-29 MAS NMR spectra of glassy $\text{Na}_2\text{Si}_4\text{O}_9$ samples quenched from high temperatures and different pressures (listed in the figure) and decompressed at room temperature. The formation of Si^{V} and Si^{VI} is indicated by the gradual emergence of peaks at -150 and -210 ppm (arrows) as the pressure is increased. The solid circles denote spinning sidebands. (Reproduced with permission of The Mineralogical Society of America from X. Xue, J. F. Stebbins, M. Kanzaki, P. F. McMillan, and B. Poe, *Am. Miner.*, 1991, **76**, 8)

This hypothesis has been confirmed for amorphous silica using ^{29}Si CP MAS NMR.⁵⁷ Since CP requires the presence of ^1H – ^{29}Si dipole couplings, only those silicon atoms that are near a hydrogen atom are detected, resulting in selective amplification of the signal due to $\text{Si}-\text{OH}$ groups. The spectra obtained are consistent with a model in which the reaction of water with the silica melt produces mostly $\text{Si}-\text{OH}$ and only few $\text{Si}(\text{OH})_2$ units.⁵⁷ In sharp contrast, CP MAS NMR studies fail to detect any $\text{Si}-\text{OH}$ groups in albite glasses, suggesting that reaction (4) is not applicable to this network.⁵⁸ The presence of water perturbs the ^{23}Na resonance significantly, suggesting that there are strong OHNa interactions.⁵⁸

Complementary information on the hydrous species has been obtained using ^1H NMR. Static spectra appear to be superpositions of a broad Pake doublet attributed to molecular H_2O and a sharper Gaussian component assigned to OH groups.^{59–62} The relative amounts of OH and molecular H_2O species have been determined by ^1H MAS NMR for a series of aluminosilicate glasses with water contents ranging from 0.5 to 8 wt.% H_2O .⁶⁰ Typical spectra are shown in Figure 17. At spinning speeds around 8 kHz, the OH groups yield a strong MAS NMR central line, because all the interactions affecting the static spectrum of the OH groups are effectively averaged by MAS. In contrast, 8 kHz MAS is unable to average the strong intramolecular dipolar interaction between the two hydrogen atoms in the water molecule. Theory predicts that the homonuclear dipolar interaction within

Figure 17 Proton MAS NMR spectra of hydrous aluminosilicate glasses containing (a) 1.5 wt.%, (b) 2.7 wt.%, and (c) 7.9 wt.% H_2O . Top: experimental spectra obtained from tremolite (T; isolated OH groups) and analcite (A; isolated H_2O molecules). Left side: experimental spectra at 8 kHz spinning speed. Right side: spinning sideband heights for the same glasses. Solid lines are experimental results, crosses are heights predicted by additive superposition of the experimental spectra of analcite and tremolite, in a ratio such that identical heights for the center bands (not shown here) result. (Reproduced with permission of The American Chemical Society from H. Eckert, J. P. Yesinowski, E. M. Stolper, and L. A. Silver, *J. Phys. Chem.*, 1988, **92**, 2055)

an isolated pair of two spins is inhomogeneous, resulting in well-defined spinning sideband patterns upon MAS. The fact that this behavior is observed experimentally suggests that the H_2O molecules in these glasses are structurally fairly isolated, and that MAS succeeds in averaging the intermolecular dipolar interactions among OH and H_2O species. The OH/ H_2O ratio can then be determined from the intensity of the sidebands relative to the center band. Figure 18 summarizes the resulting NMR-derived water speciation for various aluminosilicate glasses.⁶⁰ At low overall water contents, most of the hydrous

species are present in the form of OH groups. As the water concentration increases, the OH species concentrations level off at 2–3 wt.% H_2O , and the concentration of molecular water species increases steeply.

Another question of interest is the strength of the interaction between the hydrous species and the silica network, i.e. the hydrogen bond strength characteristics. Proton chemical shifts are known to be sensitive to hydrogen-bonding effects. As a convenient measure of the hydrogen-bonding strength, one may take the O–HO distance of the hydrogen bond.

Regression analysis of the ^1H chemical shift database on crystalline model compounds, for which those distances are well known, then allows one to estimate average hydrogen-bonding lengths in a variety of water-bearing silicate glasses. In albitic glasses the distribution is more or less uniformly centered around $d(\text{O}-\text{HO}) = 0.29\text{ nm}$.^{59,60} This result has been confirmed independently by measurements of the average ^2H quadrupolar coupling constant of D_2O -bearing glasses on the basis of a similar empirical correlation with $\text{O}-\text{DO}$ distances.⁶³ In contrast, ^1H MAS NMR spectra obtained on hydrous alkali silicate glasses reveal a decidedly bimodal behavior including rather short (0.26 nm) and longer (0.29 nm) distances.⁶⁴ The appearance of short hydrogen bonds is believed to be due to a strong association of OH groups with the nonbridging oxygen atoms in these glasses.

3.7 Sol-Gel-Prepared Glasses and Amorphous Silicas

The 'sol-gel' process used in the synthesis of oxide glasses is based upon the hydrolysis of tetraethyl orthosilicate (TEOS) or other suitable monomeric precursor species. The hydrolysis product, $\text{Si}(\text{OH})_4$, subsequently undergoes polycondensation, resulting in a heavily hydrated 'gel'. Dehydration at elevated temperatures results in densification and formation of bulk glassy material.

Figure 19 (a) Silicon-29 CP MAS NMR spectrum of silica gel. (b) Silicon-29 signal amplitude versus CP MAS contact time. Peaks A, B, and C correspond to $\text{SiO}_{4/2}$, $\text{SiO}_{3/2}\text{OH}$, and $\text{SiO}_{2/2}(\text{OH})_2$ groups, respectively. Note in particular the different CP dynamics for these three species. (Reproduced with permission of The American Chemical Society from G. E. Maciel and D. W. Sindorf, *J. Am. Chem. Soc.*, 1980, **102**, 7606)

The processes summarized in equations (5a)–(5c) proceed via many steps. Substitution of OEt by OH occurs one moiety at a time, and the polymerization of the resulting $\text{Si}^{(0)}$ species yields more highly condensed $\text{Si}^{(n)}$ species, i.e. $\text{Si}^{(1)}$ (end groups), $\text{Si}^{(2)}$ (middle groups), $\text{Si}^{(3)}$ (2D branching groups), and $\text{Si}^{(4)}$ (3D branching groups). These species are analogous to those introduced in Section 3.1, except that they are terminated by OH rather than O^- .

NMR has proven to be an excellent method for monitoring the various stages of the sol-gel process. Since the hydrolysis and the initial stages of polymerization of the hydrolysis products occur in homogeneous solution, they can be easily followed by standard liquid state ^{29}Si NMR.⁶⁵ In contrast, studies of the dried and dehydrated gels require solid state NMR methodology. Figure 19(a) demonstrates that ^{29}Si chemical shifts differentiate generally quite well between $\text{SiO}_{4/2}$, $\text{Si}(\text{OH})\text{O}_{3/2}$, and $\text{Si}(\text{OH})_2\text{O}_{2/2}$ species (peaks A, B, and C, respectively).⁶⁶ The peak assignments are based on the

Figure 20 Static ^{29}Si NMR spectra of an aging gel kept in a closed vial at room temperature after refluxing for 3 h and stripping to 1.1 g ml^{-1} , as a function of aging time. The molar composition of the parent solution was $\text{TEOS}/\text{H}_2\text{O}/\text{ethanol}/\text{HCl} = 1/16/4.0/0.01$. (Reproduced with permission of Elsevier Science Publishers BV from A. J. Vega and G. W. Scherer, *J. Noncryst. Solids*, 1989, **111**, 153)

different CP dynamics of the silanol groups compared with those of silicon atoms more removed from hydrogen. This is demonstrated by the variable contact time experiments in Figure 19(b) CP MAS experiments with short contact times tend to enhance the signals of the hydroxyl-bound silicon atoms, whereas ^{29}Si MAS NMR studies result in quantitatively representative spectra.

The influence of specific experimental conditions on the network structure and the fate of residual hydrous species during the various stages of the gel–glass transition have been studied in detail by Vega and Scherer.⁶⁷ Figure 20 shows an experiment monitoring the aging process of an SiO_2 gel over a period of several months. The spectra show three peaks, assigned to $\text{Si}^{(2)}$, $\text{Si}^{(3)}$, and $\text{Si}^{(4)}$ species. The speciation changes remarkably little upon aging and syneresis, indicating that the polymerization is to a large degree arrested at the gelation stage. The peak deconvolution on the final glass samples attained after prolonged aging shows $\text{Si}^{(4)}$ and $\text{Si}^{(3)}$ in roughly equal proportions and a small amount (<5%) of $\text{Si}^{(2)}$ species. This corresponds to a final OH content of 0.5 to 0.6 units per silicon. This conclusion is confirmed by complementary ^1H NMR studies, which also serve to characterize the motional properties of the hydrous species.⁶⁷

4 BORATE GLASSES

While technologically of less interest, borate glasses have been the subject of intense structural investigations during the past three decades. Specific topics of study have been (i) structural implications of the Lewis acid character of boron oxide, resulting in increased polymerization by basic oxides, (ii) the description of borate glasses in terms of molecular cluster units known from the crystal chemistry of borates, and (iii) the interaction of boron oxide with other network formers and intermediate oxides in borosilicate, borophosphate, and boroaluminate glasses. Much of the early NMR work on glasses (prior to the early 1970s) concentrated on borate systems, where the only technique widely available then, low-field CW NMR, proved to be an ideal structural tool for probing short-range order. In spite of the availability of more modern techniques, this remains true to the present date.

4.1 Site Distribution in Glassy Boron Oxide

The structure of glassy B_2O_3 is generally viewed to consist largely of six-membered boroxol rings in addition to loose BO_3 units. While previous CW NMR studies of ^{11}B and ^{10}B were unable to resolve distinct resonances for these sites, this has been accomplished recently using pure NQR. As shown in Figure 21(a), the NQR spectrum reveals two distinct boron sites with quadrupolar frequencies ($\chi/2$) of 1358

Figure 21 Two recent experimental ^{11}B NQR/NMR results relating to the structure of glassy B_2O_3 . (a) CW ^{11}B NQR, both experimental and predicted based on previous ^{11}B NMR studies. (Reproduced with permission of Elsevier Science Publishers BV from S. J. Gravina, P. J. Bray, and G. L. Petersen, *J. Noncryst. Solids*, 1990, **123**, 165). (b) 2D ^{11}B DAS NMR, carried out on an isotopically depleted sample. (Reproduced with permission of Elsevier Science Publishers BV from R. E. Youngman and J. W. Zwanziger, *J. Noncryst. Solids*, 1994, **168**, 293). The NQR and DAS methods detect two different types of boron sites, assigned to boron atoms within boroxol rings (majority site) and loose BO_3 groups (minority site)

and 1305 kHz, which are assigned to boron atoms inside of and outside of boroxol rings, respectively.⁶⁸ The peak ratio suggests that 85% of all boron atoms are contained within boroxol rings. Very similar results have been obtained most recently using the ^{11}B DAS NMR technique [Figure 21(b)].⁶⁹ The nuclear electric quadrupole coupling constants obtained for these sites from the anisotropic dimension in the DAS experiment are in excellent agreement with the values obtained from pure NQR.

4.2 Binary Alkali and Alkaline Earth Borate Glasses

4.2.1 Spectroscopic Approaches

Introduction of alkali oxide into glassy B_2O_3 results in the formation of four-coordinate boron atoms (B^{IV} units), as well as three-coordinate boron atoms associated with one to three nonbridging oxygen atoms ($\text{B}^{\text{III}(0-2)}$ units). Low-field CW NMR techniques have been very effective in differentiating quantitatively between these principal types of boron nearest-neighbor environments, exploiting differences in the magnitude and symmetry of the nuclear electric field gradient at the boron sites. These differences are summarized in Figure 22. Symmetric-trigonal $\text{BO}_{3/2}$ (B^{III_s}) groups with D_{3h} symmetry are characterized by χ around 2.6 MHz and an asymmetry parameter near zero. Asymmetric-trigonal $\text{BO}_{2/2}\text{O}^-$ or $\text{BO}_{1/2}(\text{O}^-)_2$ (B^{III_a}) groups have χ around 2.6 MHz and $\eta \sim 0.6$, while four-coordinate $\text{BO}_{4/2}^-$ (B^{IV}) groups are characterized by substantially smaller electric field gradients. At low field strengths, both types of three-coordinate boron sites show well-defined powder patterns due to second-order quadrupolar perturbations, whereas four-coordinate $\text{BO}_{4/2}^-$ groups yield sharp lines with little evidence of quadrupolar broadening.⁷⁰

Additional structural insights into the conversion of the B_2O_3 network by alkaline oxides have recently been obtained by the CW NQR method,⁷¹ revealing the successive destruction of boroxol groups upon addition of alkali oxide network modifiers, and their virtually complete elimination near 20 mol% alkaline oxide. For individually resolved sites, it appears that the distribution functions of the quadrupole coupling parameters are substantially narrower than previously believed, suggesting the presence of some intermediate-range order. This result confirms the general view held that alkali borate glasses comprise statistical assemblies of various ring structures present in crystalline borates.

While the quantitative distinction between the various boron sites shown in Figure 22 has been accomplished well by ^{11}B CW NMR, this method suffers from low intrinsic detection sensitivity. An additional problem is the increasing lack of availability of such spectrometers. Standard FT wideline experiments at higher fields have generally given less satisfactory results. With increasing field strength, the width of the B^{III} resonance decreases (due to diminished second-order quadrupolar effects), while that of the B^{IV} resonance increases (due to increased chemical shift dispersion), hence making the spectral separation more difficult. Even with high-field, high-speed MAS NMR one observes substantial peak overlap, because the isotropic chemical shift difference between the B^{III} and the B^{IV} units ($\sim 15\text{--}20$ ppm) is largely canceled by their respective difference in $\delta^{(2)}$, which has opposite sign.

Figure 22 Boron sites in borate glasses and their derivative ^{11}B NMR spectra as detected by CW wideline NMR (Reproduced by permission of Pergamon Press from H. Eckert, *Prog. Nucl. Magn. Reson.*, 1992, **24**, 159)

This problem has been recently addressed successfully by focusing the attention on the first-order satellite transitions (SATRAS NMR). From theory it is known that for spin- $\frac{3}{2}$ nuclei the second-order shifts associated with the first-order quadrupolar satellites are twice as large as those for the central transition, and, furthermore, have positive sign.⁷² An important consequence is that the spectral resolution between B^{III} and B^{IV} units is enhanced for the satellite transitions because the differences in δ_{iso} and $\delta^{(2)}$ now possess the same sign. Important new results demonstrating this resolution improvement are shown in Figure 23.⁷³ Besides quantitative reliability, the SATRAS method affords accurate chemical shift and quadrupolar coupling information on the various types of boron sites.

4.2.2 Experimental Results on Binary Systems

Using NMR strategies outlined above, quantitative site ratios $\text{B}^{\text{III}_s}:\text{B}^{\text{III}_a}:\text{B}^{\text{IV}}$ have been determined systematically for a huge number of binary and ternary borate glass systems. Typically, the fraction N_4 of four-coordinate boron atoms is plotted as a function of R , the molar ratio of network modifier

Figure 23 Boron-11 SATRAS NMR results on a glass containing 33 mol% Li_2O and 67 mol% B_2O_3 . (a) Central transition, (b) 13th sideband (to high frequency) of the satellite transition, (c) higher frequency part of the satellite transition spinning sideband spectrum. (Reproduced with permission of Elsevier Science Publishers BV from L. Van Wüllen and W. Müller-Warmuth, *Solid State NMR*, 1993, **2**, 279)

to network former. At low network modifier concentrations ($R \leq 0.5$), $N_4 = R$, i.e. each oxide ion introduced into the borate network converts two boron atoms from threefold to fourfold. At higher values of R , N_4 decreases again, and the successive growth of signal components due to B^{IIIa} units marks the increasing production of nonbridging oxygen species. Recent studies, using improved lineshape deconvolution procedures, suggest special cation effects for alkali borate glasses.⁷⁴ Figure 24 suggests that N_4 for a given R value decreases with increasing cation size. In addition, mixed alkali glasses show systematically reduced N_4 values, indicating that B^{IIIa} units compete more successfully with B^{IV} units.⁷⁴

4.2.3 Experimental Results on Ternary Systems

The presence of additional network formers or of intermediate oxides has a profound influence on the boron speciation, and such effects have been widely documented by ^{11}B CW NMR for many ternary systems, including borophosphate,⁷⁵ borosilicate,⁷⁶ and borovanadate⁷⁷ glasses. A simple phase diagram scheme has been proposed to rationalize the experimental results.^{78,79} In essence, this scheme uses the lever rule to predict N_4 for a given glass from the experimental N_4 values of certain 'standard' glasses, whose compositions correspond to those of congruently melting compounds in the ternary phase diagram. If the phase diagram is not well known, however, additional assumptions have to be introduced with regard to the composition of such 'standard' glasses. Whether or not such choices can always be rationalized in a plausible way, the predictive schemes developed by these authors appear to work well for a variety of ternary borate glasses and can serve as an

Figure 24 Dependence of N_4 on R as a function of the alkali ion in alkali borate glasses. $\circ$, lithium borate; $\blacktriangle$, sodium borate; $\square$, potassium borate; $\blacksquare$, rubidium borate; $\triangle$, cesium borate glasses. (Reproduced with permission of Elsevier Science Publishers BV from J. Zhong and P. J. Bray, *J. Noncryst. Solids*, 1989, **111**, 67)

alternative for the (less general) empirical relations used previously, particularly in the borosilicate systems⁷⁶ for describing the dependence of N_4 on composition.

Aluminoborate glasses of the composition $\text{M}_{(2)}\text{O}-\text{Al}_2\text{O}_3-\text{B}_2\text{O}_3$ (M = alkali or alkaline earth metal) have been studied in particular detail. Incorporation of aluminum into alkali and alkaline earth borate glasses at constant R leads to a considerable reduction in N_4 .^{80,81} This observation indicates that part of the cations are associated with four-coordinate AlO_4^- units, at the expense of the boron conversion process. Not all of the alkaline oxide is directed towards aluminum, however, because even in glasses with an $\text{M}_{(2)}\text{O}/\text{Al}_2\text{O}_3$ ratio of unity, a substantial fraction of the boron atoms remain four-coordinate. This finding is consistent with ^{27}Al MAS NMR data, which show that a sizable fraction of the aluminum atoms are present as Al^{V} and Al^{VI} .⁸² In interpreting the aluminum speciations, Brow and co-workers estimate the stability of various oxygen nearest-neighbor environments on the basis of bond valence considerations.⁸³ Maximum stability is expected if the bond valence sums (charge divided by coordination number) of the cations next to an oxygen site are close to +2 for a neutral oxygen site, and +1 for a nonbridging oxygen site. Such considerations show, for instance, that $\text{B}^{\text{IV}}-\text{O}-\text{B}^{\text{IV}}$ and $\text{Al}^{\text{IV}}-\text{O}-\text{Al}^{\text{IV}}$ connectivities are less stable than $\text{B}^{\text{III}}-\text{O}-\text{Al}^{\text{IV}}$ linkages, and that three-coordinate oxygen atoms must exist to explain the presence of Al^{V} and Al^{VI} . As shown in Figure 25 the bond valence concept is also useful for explaining chemical shift trends for the Al^{IV} site. The shift values observed experimentally (55–60 ppm) are much more consistent with $\text{Al}^{\text{IV}}-\text{O}-\text{B}^{\text{III}}$ linkages than with the $\text{Al}^{\text{IV}}-\text{O}-\text{B}^{\text{IV}}$, $\text{Al}^{\text{IV}}-\text{O}-\text{Al}^{\text{IV}}$, and $\text{Al}^{\text{IV}}-\text{O}-\text{Al}^{\text{VI}}$ linkages previously proposed. These conclusions are also in agreement with the stability arguments outlined above. Most recently, SATRAS NMR has allowed a much cleaner distinction between the three aluminum sites in aluminoborate glasses.⁸⁴ This is expected from theory, predicting that second-order

Figure 25 Correlation of the ^{27}Al chemical shift ranges observed for Al^{IV} in framework structure crystalline model compounds (four network next-nearest neighbors) with the bond valence sum ('bond strength') of the next-nearest neighbor cation. From this plot it is predicted that an Al^{IV} species linked to four B^{IV} or to four B^{III} species should resonate at 75 and 55 ppm, respectively. (Reproduced with permission of The American Ceramic Society from B. C. Bunker, R. J. Kirkpatrick, R. K. Brow, G. L. Turner, and C. Nelson, *J. Am. Ceram. Soc.*, 1991, **74**, 1430)

quadrupolar broadening effects are greatly reduced for the $\pm\frac{1}{2} \rightarrow \pm\frac{3}{2}$ satellite transitions of spin $I = \frac{5}{2}$ nuclei.⁷²

5 PHOSPHATE GLASSES

The local order in phosphate glasses is described, in a manner very similar to silicate glasses, in terms of four individual $\text{P}^{(n)}$ sites ($n \leq 3$), varying in the number of bridging oxygen atoms. As illustrated in Figure 26, these sites are easily distinguished by ^{31}P isotropic and anisotropic chemical shift parameters. Quantitative deconvolution of the ^{31}P MAS NMR spectra reveal that in binary alkali and silver phosphate glasses^{85,86} and in alkaline earth phosphate glasses⁸⁷ the $\text{P}^{(n)}$ site distribution follows the binary model. Since water acts as a network modifier in these hygroscopic glasses, a precise analysis of NMR spectra of these glasses requires the exact water content to be known. Most recently, the binary model has been confirmed for alkali phosphate glasses prepared and stored under rigorously anhydrous conditions.⁸⁸ The binary model is also substantiated in the fast ionic conductors based on $\text{Ag}_2\text{O}-\text{AgI}-\text{P}_2\text{O}_5$ glasses, which show excellent chemical shift resolution for the various $\text{P}^{(n)}$ species. Here, the AgI component does not participate in the network modification, but is dispersed throughout the glass structure.⁸⁶

Zwanziger and co-workers have utilized the VACS Y technique to correlate specific isotropic chemical shifts with the corresponding anisotropic chemical shift information in ionically conducting silver phosphate glasses.⁸⁹ Figure 27 shows an interesting result for a glass with the composition $(\text{Ag}_2\text{O})_{41}(\text{AgI})_{39}(\text{P}_2\text{O}_5)_{20}$. The MAS NMR spectrum shows a low-intensity peak at 23.6 ppm, assigned to PO_4^{3-} ($\text{P}^{(0)}$) groups, and a dominant resonance centered around 3 ppm, assigned to $\text{P}_2\text{O}_7^{4-}$ ($\text{P}^{(1)}$) groups. Both peaks are broadened by a distribution of isotropic chemical shifts, reflecting the inherent disorder in the glass. As intended, VACS Y is able to recover the individual CSA information for these two

Figure 26 Phosphorus sites in alkali phosphate glasses and their wide-line ^{31}P NMR anisotropic chemical shift powder patterns. The terminology used here is analogous to that defined in Figure 7(a) (Reproduced by permission of Pergamon Press from H. Eckert, *Prog. Nucl. Magn. Reson.*, 1992, **24**, 159)

distinct sites. Furthermore, the chemical shift tensor elements for the $\text{P}^{(1)}$ resonance depend on the exact position within the isotropic chemical shift distribution. The low-frequency shoulder of the $\text{P}^{(1)}$ resonance is correlated with a nonaxially symmetric chemical shift tensor, revealing the presence of distinct, more distorted pyrophosphate groups. The ability of VACS Y to enhance the resolution between sites whose MAS NMR centerbands overlap makes it a potentially very powerful tool for the investigation of many other spin- $\frac{1}{2}$ nuclei in glasses and other disordered materials that give rise to very poorly resolved MAS NMR spectra.

Excellent site resolution has been observed by ^{31}P MAS NMR in borophosphate and (to a lesser extent) aluminophosphate glasses.⁹⁰⁻⁹³ Considering next nearest-neighbor environments, these glasses may contain (depending on composition) up to 11 $\text{P}_m^{(n)}$ sites, where m is the number of boron or aluminum next-nearest neighbors ($m \leq n$). Among these sites, features not known for binary alkali phosphate glasses are the tetrahedral, fully bridging $\text{P}_4^{(4)}$ sites, well known in crystalline BPO_4 and AlPO_4 . The ^{31}P MAS NMR spectra of silver

Figure 27 Phosphorus-31 VACS Y NMR results obtained on a glass containing 41 mol% Ag_2O , 39 mol% AgI , and 20 mol% P_2O_5 . (a) Overall contour plot. (b)–(e) Slices through the VACS Y spectrum at isotropic shifts of (b) 23.6 ppm, (c) 8.1 ppm, (d) 3.3 ppm, and (e) -7.3 ppm. (Reproduced with permission from J. W. Zwanziger, K. K. Olsen, and S. L. Tagg, *Phys. Rev. B*, 1993, **47**, 14618)

borophosphate glasses were found to be exceptionally well resolved,⁹⁰ permitting a quantitative distinction between various of these sites. In contrast, only partial site resolution is observed for sodium aluminophosphate glasses.^{91–93} For the sodium aluminophosphate glasses, bond valence arguments predict that the interaction of a $\text{P}^{(2)}$ (metaphosphate) site is more favorable with Al^{VI} than with Al^{IV} .⁹³ The compositional dependence of the average aluminum coordination number is summarized in Figure 28, revealing a distinct influence of the total oxygen/phosphorus ratio. Contrary to previous assumptions, the ^{27}Al NMR spectra indicate that the majority of aluminum sites are six-coordinate in most of the materials within the glass-forming region. Four-coordinate AlPO_4 -like sites are only observed at the highest oxygen/phosphorus ratios.

6 CHALCOGENIDE GLASSES

6.1 Binary Silicon Chalcogenide Glasses

Glassy SiS_2 and SiSe_2 form structures based on $\text{SiX}_{4/2}$ tetrahedra interconnected by both corner- and edge-sharing, in

violation of the traditional continuous random network model, which explicitly excludes any connectivities different from corner-sharing. The ^{29}Si MAS NMR spectra show three broad peaks, which can be assigned to silicon tetrahedra sharing edges with no, one, or two adjacent tetrahedral units. These sites have been denoted $\text{E}^{(0)}$, $\text{E}^{(1)}$, and $\text{E}^{(2)}$, respectively.⁹⁴ Similar kinds of materials can be prepared by plasma-enhanced chemical vapor deposition (PECVD) from SiH_4 and H_2S . Compared with the bulk glass, the PECVD samples possess higher concentrations of $\text{E}^{(0)}$, and reduced concentrations of $\text{E}^{(2)}$ species. This structural speciation is critically influenced by the $\text{H}_2\text{S}/\text{SiH}_4$ flow rate ratio under synthesis conditions. Thus, PECVD offers the opportunity of controlling the ratio of corner-shared to edge-shared $\text{SiS}_{4/2}$ tetrahedra in the final product.⁹⁵ This is not possible in molten state synthesis, where changes in the silicon/sulfur melt composition just produce different relative amounts of segregated phases consisting of glassy SiS_2 and elemental sulfur.⁹⁶

The structure of glassy SiSe_2 closely resembles that of a low-temperature crystalline SiSe_2 phase stable near 500 °C, close to the temperature where molten SiSe_2 undergoes its glass transition.⁹⁷ Si–Se glasses with higher selenium contents and SiSe_2 – P_2Se_5 glasses show increased fractions of the $\text{E}^{(0)}$ component, whereas the $\text{E}^{(2)}$ component is essentially absent.⁹⁸ These results indicate a continuous distribution of silicon microstructures, including the presence of Si–Se–Se and Si–Se–P linkages.

6.2 Lithium Thiosilicate and Selenosilicate Glasses

Glasses in the system $(\text{Li}_2\text{S})_x(\text{SiS}_2)_{1-x}$ ($0.4 \leq x \leq 0.6$) are interesting because of their high ionic conductivities. These systems have been studied as interesting test cases on whether the compositional analogy of these glasses to binary alkali silicate systems translates into structural analogy as well. The NMR results show that introduction of Li_2S into glassy SiS_2 initially reduces the extent of edge-sharing markedly, and the $\text{E}^{(2)}$ species have disappeared for the composition $x = 0.30$. Figure 29 illustrates the network modification scheme developed on the basis of the NMR data.⁹⁹ The destruction of edge-sharing units by Li_2S (represented by diagonal arrows) results in the formation of nonbridging sulfur atoms. In the compositional region where the most stable glasses form ($0.38 < x < 0.6$) the $\text{E}^{(n)}$ distribution remains approximately constant, with an $\text{E}^{(0)}/\text{E}^{(1)}$ ratio of $\sim 2.5:1$. Extension of these investigations to the system Li_2Se – SiSe_2 reveals qualitatively many of the same features, except that the chemical shift discrimination between various $\text{Si}^{(n)}$ units is markedly improved here, and semiquantitative species concentrations can be derived from the ^{29}Si MAS NMR spectra.¹⁰⁰ Parallel studies of crystallized samples reveal that with an increasing number of bridging selenium atoms in the $\text{Si}^{(n)}$ notation the chemical shifts become less negative, the opposite trend as observed in the silicates.

6.3 The Phosphorus–Selenium System

The phosphorus–selenium system is characterized by a pronounced tendency toward vitrification. Glasses are formed over a wide compositional region, from 0–52 and 62–80 mol%

Figure 28 (a) Typical ^{27}Al MAS NMR spectra of sodium aluminophosphate glasses. Compositions are denoted by the molar ratio of $\text{Na}_2\text{O}:\text{Al}_2\text{O}_3:\text{P}_2\text{O}_5$. (b) Dependence of the average aluminum coordination number on the O:P ratio in these glasses. (Reproduced with permission of The American Ceramic Society from R. K. Brow, R. J. Kirkpatrick, and G. L. Turner, *J. Am. Ceram. Soc.*, 1993, **76**, 919)

P. MAS NMR chemical shifts clearly distinguish between $\text{Se}=\text{PSe}_{3/2}$ and three-coordinate phosphorus atoms; however, they do not allow one to identify the number of phosphorus or selenium nearest neighbors unambiguously.¹⁰¹

The above problem has been successfully addressed by a detailed analysis of the spin echo decay. Due to the substantial difference in the strength of the homonuclear dipole–dipole interactions, the spin echo decays for phosphorus atoms coordinated to selenium only and those for the phosphorus atoms with a phosphorus nearest neighbor are distinctly different. The experimental results indicate that P–P bonds contribute to the glass structure above 25 at.% P, and their contribution can be quantitatively evaluated. The combined analysis of ^{31}P spin echo and MAS NMR results then yields the final phosphorus speciation shown in Figure 30.¹⁰² There is a definite preference toward formation of P–Se over P–P bonds. It is important to realize that all of the above structural findings, obtained on melt-quenched glasses,

reflect molten state chemical equilibria that are frozen in at the glass transition temperature, T_g . To understand these speciations further, and to predict the influence of quenching rates on glass structures, it is important to characterize these equilibria and the thermodynamic parameters involved. Consider, for instance, the compositional dependence of the P^{IV} mole fraction, i.e. the fraction of $\text{Se}=\text{PSe}_{3/2}$ groups in the phosphorus–selenium system, replotted in Figure 31. The data can be consistently described assuming a melt equilibrium model of the form (6)

with an equilibrium constant K_1 around $0.8 (\text{at. fraction})^{-1}$. Recent in situ high-temperature NMR studies have shown that in the melt K_1 consistently decreases with increasing temperature.¹⁰³ The associated reaction enthalpies and entropies have been determined as -5 kJ mol^{-1} and -17 J

Figure 29 (a) Silicon-29 MAS NMR spectra and (b) network modification scheme developed for lithium thiosilicate glasses. (Reproduced with permission of Elsevier Science Publishers BV from H. Eckert, J. H. Kennedy, A. Pradel, and M. Ribes, *J. Noncryst. Solids*, 1989, **113**, 287)

$\text{mol}^{-1} \text{K}^{-1}$, respectively. A second temperature-dependent chemical equilibrium is apparent in glasses containing ≥ 40 at.% P, resulting in the appearance of molecular P_4Se_3 cluster units, whose spectral contribution grows with increasing temperature. This depolymerization reaction has been modeled in terms of scheme (7)

The temperature dependence of the associated equilibrium constant indicates a reaction enthalpy of 50 kJ mol^{-1} .¹⁰³

Complementary thermodynamic and kinetic data have been obtained using variable-temperature ^{77}Se NMR studies, the results of which are shown in Figure 32.¹⁰³ At low

The solid curve is calculated assuming an equilibrium of the kind $\text{PSe}_{3/2} + \text{Se} \rightleftharpoons \text{Se}=\text{PSe}_{3/2}$ with an equilibrium constant K_1 of $0.83 (\text{at. fraction})^{-1}$ (Reproduced by permission of Pergamon Press from H. Eckert, *Prog. Nucl. Magn. Reson.*, 1992, **24**, 159)

Figure 32 (a) Temperature-dependent ^{77}Se NMR spectra of a phosphorus-selenium glass containing 20 at.% P. The resonances observed at low temperatures near 1380 and 1150 ppm correspond to selenium-only and phosphorus-bonded selenium atoms, respectively. (b) Temperature dependence of ^{77}Se chemical shifts in various phosphorus-selenium melts. □, liquid selenium; ◆, 5 at.% P glass; △, 13 at.% P glass; ●, 20 at.% P glass; ○, 32 at.% P glass; ▲, 40 at.% P glass (Reproduced with permission of The American Chemical Society from R. Maxwell and H. Eckert, *J. Am. Chem. Soc.*, 1994, **116**, 682)

temperatures, distinct resonances for phosphorus-bonded and selenium-only bonded selenium atoms can be resolved, which coalesce approximately 100 K above T_g into a single resonance due to chemical exchange on the NMR timescale. The average ^{77}Se chemical shift measured in the fast exchange limit reflects the quantitative distribution of Se–Se versus Se–P bonding in the glass; the same information previously also obtained (albeit with lower accuracy) by ^{31}P – ^{77}Se spin echo double resonance NMR.¹⁰⁴ When combined with the phosphorus speciations from ^{31}P NMR, these data allow important conclusions about intermediate-range order. Figure 33 illustrates that the data are most compatible with a glass structure model in which PSe_n units and Se–Se units are randomly linked, with a slight preference for P–Se–P bridges.¹⁰⁵ The data also clearly rule out previous structural

models¹⁰⁶ based on P_4Se_n clusters embedded in a selenium-rich matrix.

6.4 Ternary Metal Thiophosphate Glasses

Phosphorus-31 MAS NMR studies have been undertaken on a variety of ionically conductive glasses derived from the pseudobinary systems Li_2S – P_2S_5 ¹⁰⁷ and Ag_2S – P_2S_5 .¹⁰⁸ In many of these glasses, large chemical shift differences between crystalline and glassy phases are observed, indicating substantial differences in short-range order.

Glass with the composition $\text{Li}_4\text{P}_2\text{S}_7$, for example, disproportionates on crystallization, undergoing the transformation from a pyrothiophosphate to a hexahypothiodiphosphate with a phosphorus–phosphorus bond.

Also, the crystalline phases $\text{Ag}_2\text{P}_2\text{S}_6$ and $\text{Li}_2\text{P}_2\text{S}_6$ form dimers of edge-sharing $\text{PS}_{4/2}$ tetrahedra, which do not appear to be represented in the glassy state. The structural conclusions are summarized in Figure 34. Local environments of glassy thiophosphates generally resemble those present in

Figure 34 (a) Phosphorus-31 MAS NMR spectra and (b) structural interpretations for glasses in the system $(\text{Ag}_2\text{S})_x-(\text{P}_2\text{S}_5)_{1-x}$. (Reproduced with permission of The American Chemical Society from Z. Zhang, J. H. Kennedy, and H. Eckert, *J. Am. Chem. Soc.*, 1992, **114**, 5775)

phosphate glasses, whereas there are large differences in the local environments between crystalline thiophosphates and crystalline phosphates.

7 AMORPHOUS SEMICONDUCTORS

The issue of glass formation in amorphous semiconductors, where all of the atoms are tetrahedrally coordinated, has been the subject of considerable research activity. Molecular modeling has been used to 'amorphize' the cubic silicon lattice by the introduction of random bond switches, which alter the ring statistics of the original lattice and newly introduces five- and seven-membered rings.¹⁰⁹ Unfortunately, it has been impossible to detect such structural defects by solid state NMR. The ^{29}Si NMR spectra of amorphous silicon materials are largely dominated by hydrogen doping effects, and ^1H NMR has been used extensively to study the spatial arrangements of the hydrogen atoms¹¹⁰ (see also *Amorphous Silicon Alloys*).

For heteropolar structures such as III–V or II–IV–V₂ lattices, the presence of such odd-membered rings necessarily

implies the formation of homopolar (such as V–V) bonds. Past attempts to identify such 'wrong bonds' in amorphous GaAs by $^{69,71}\text{Ga}$ and ^{75}As NMR have only met with limited success, because the lineshapes perturbed by the quadrupolar interaction for these nuclei are difficult to interpret.¹¹¹ However, there are several related glass-forming systems, most notably CdGeAs_2 , CdGeP_2 , and their corresponding alloys, where this question can be examined. In their crystalline forms, these materials arrange themselves in the chalcopyrite structure, a simple superstructure of the silicon lattice. For these materials, the question of homopolar bond formation has been studied by measuring ^{31}P – ^{31}P dipole–dipole couplings, which are very sensitive to the formation of P–P and P–Cd bonds. Figure 35 shows the comparison of the experimental ^{31}P spin echo decay data with simulations for a chemically ordered chalcopyrite structure, a random distribution of phosphorus atoms over all the lattice sites, and an additive superposition of both. The experimental results are quantitatively consistent with the occurrence of P–P bonds in glassy CdGeP_2 , albeit at a substatistical level.^{112,113} The formation of pnictogen–pnictogen bonds in the glassy state of CdGeP_2 and CdGeAs_2 is facilitated by the high electronegativity of germanium. In contrast, glass formation is strongly inhibited in the analogous systems based on silicon and tin, which have significantly lower electronegativities and thus form more polar bonds with pnictogens.

Acknowledgments

I would like to thank my past and present graduate students, Dr. Nandini Das, Dr. Delphine Davis, Dr. Deanna Franke, Becky Gee, Christopher Hudalla, Dr. David Lathrop, Dr. Carri Lyda, Dr. Robert Maxwell, Dr. Kelly Moran, Dr. Robert Shibao, and Yin Xia for all the contributions they have made to the work partly reviewed here. This review contains excerpts of their Ph.D. dissertations. I would like to thank further the numerous undergraduates who have worked in our laboratory, and my collaborators, Dr. Annie Pradel and Dr. Michel Ribes (University of Montpellier), Dr. J. H. Kennedy (Professor Emeritus, UCSB), Dr. Galen Stucky (UCSB), Dr. James Yesinowski (Naval Research Laboratory),

and Dr. Edward Stolper (California Institute of Technology) for their contributions to joint work that is discussed and cited here. Our research program is supported by the National Science Foundation, grants DMR 89-13738 and 92-21197. This support is gratefully acknowledged.

Biographical Sketches

Hellmut Eckert, *b* 1956. Diplom, 1978, University of Münster, Germany, Ph.D., 1982, University of Münster, Germany. Introduced to NMR by W. Müller-Warmuth. Postdoctoral research associate, Rutgers University, USA (with R. H. Herbert, 1982–84, staff scientist, California Institute of Technology 1984–87 (with S. I. Chan and J. P. Yesinowski), Faculty in Chemistry, University of California, Santa Barbara, USA 1987–present. Approx. 130 publications. Research specialties: the experimental development of heteronuclear X–Y solid state NMR techniques and the application of solid state NMR techniques to inorganic disordered materials, including glasses, ceramics, and semiconductors.

Amorphous Silicon Alloys

1 INTRODUCTION

Amorphous semiconductors are used extensively in electronic and optoelectronic devices. While properties of amorphous semiconductors such as carrier lifetime are usually inferior to those of crystalline semiconductors, several unique characteristics make amorphous semiconductors the materials of choice for applications such as solar cells, large area image sensors, and thin-film transistors for liquid crystal displays. Amorphous semiconductors can be deposited over large areas using plasma-enhanced chemical vapor deposition, their photo-conductivities are many orders of magnitude higher than their dark conductivities, and their properties can be tailored by doping and alloying. Amorphous hydrogenated silicon (a-Si:H) is the most studied amorphous hydrogenated semiconductor. Electronic device-quality material has an optical band gap of ~ 1.75 electron volts (eV), and a paramagnetic defect density of less than 10^{16} cm^{-3} . A particularly attractive feature of a-Si:H is its high photoconductivity-to-dark conductivity ratio, which is often greater than 10^5 . The technological applications of a-Si:H range from thin film transistors to solar photovoltaic devices.¹

Amorphous hydrogenated semiconductors are heterogeneous. To the eye, or even with the aid of an optical microscope, thin films of a-Si:H appear smooth and homogeneous. However, as the scale of observation decreases to less than $1 \mu\text{m}$ an inhomogeneous structure becomes evident. Transmission and scanning electron microscopy have revealed lamellar structures, columns, and voids in amorphous hydrogenated semiconductors.² Even 'device-quality' amorphous silicon has a heterogeneous microstructure.³

Many of the technological applications of amorphous silicon are restricted by light-induced metastable defects. In fact, the highest quality materials tend to exhibit the greatest changes upon light exposure. Understanding these light-induced changes, and reducing or exploiting them, has been the object of a significant fraction of the research on amorphous silicon and its alloys. Current opinion links these light-induced defects with the microstructural features of a-Si:H.

This article presents examples of the use of nuclear magnetic resonance to investigate technological and scientific issues concerning amorphous hydrogenated silicon and its alloys. Nuclear magnetic resonance (NMR) has been an important

tool in characterizing the microstructure of a-Si:H and related materials, and its application has been discussed in several earlier reviews.²⁻⁷

2 HYDROGEN- AND DEUTERIUM-RELATED MICROSTRUCTURE (^1H , ^2D)

From the first preparation of a-Si:H thin films, certain issues have attracted attention. It was found that a-Si (no hydrogen), prepared by evaporation or sputtering techniques, was of little interest as an electronic material. However, when a-Si:H was prepared by the glow-discharge decomposition of silane gas, a much improved material was obtained. NMR experiments helped to answer questions about hydrogen content and distribution, and the effects of materials production conditions on hydrogen in a-Si:H. The current consensus is that a-Si:H can contain as much as 50 at.% hydrogen, but that 8–18% is typical for high electronic quality materials. The hydrogen is distributed in three environments: a dilute 'phase' consisting of silicon monohydride groups greater than three or four lattice spacings apart, a clustered 'phase' in which hydrogen nuclei bonded as silicon mono-, di-, or trihydride are close enough together to produce ^1H NMR linewidths of 20–30 kHz, and a small amount of trapped molecular hydrogen.

^{19}F NMR studies of fluorinated amorphous silicon have been discussed in an earlier review.⁵

2.1 ^1H NMR

2.1.1 Free Induction Decay Spectra

Most NMR experiments have studied hydrogen because of the large magnetic moment and near 100% natural abundance of the ^1H isotope. ^1H NMR free induction decay spectra can be used to determine hydrogen contents and distributions in a-Si:H in a quantitative, nondestructive manner.

The most recognizable characteristic of the ^1H NMR spectra of a-Si:H obtained at room temperature is the two-component lineshape illustrated by Figure 1.⁸⁻¹⁰ The overlapping broad and narrow lineshapes indicate that two different spin–spin relaxation time constants (T_2) are involved. The fast-relaxing component has a Gaussian shape and is typically 25–30 kHz wide. This lineshape and width are indicative of homonuclear dipole coupling among hydrogen nuclei, leading to the conclusion that the broad component represents 'clustered' hydrogen, or a hydrogen-rich environment. The slow-relaxing component has a Lorentzian shape and is typically 1–5 kHz wide. This lineshape and width are indicative of nuclei which relax by mechanisms other than dipolar coupling, leading to the assignment of this component to isolated hydrogen nuclei, or silicon monohydride groups. The T_2 values for the two environments can be estimated from the linewidths. The hydrogen-rich phase has $T_2 \approx 20 \mu\text{s}$ while the hydrogen-poor phase has $T_2 \approx 60 \mu\text{s}$. The extent of the hydrogen-poor phase may be as large as 88% of the

Figure 1 ^1H free induction decays (top) and the corresponding Fourier-transformed spectra (bottom) for two a-Si:H samples. The two-component nature of the ^1H NMR spectrum is clearly demonstrated. (Reproduced by permission of the authors and The American Physical Society from W. E. Carlos and P. C. Taylor, *Phys. Rev. B*, 1982, **26**, 3605)

material volume, depending upon the amount of hydrogen clustering.¹¹

2.1.2 Investigations of the Broad Line

The assignment of the broad line to dipole-coupled hydrogen nuclei was confirmed by a hole-burning experiment.¹⁰ A saturation pulse applied at a frequency well-displaced from the line center only saturated the broad line. This result showed that the hydrogen nuclei in the broad line were dipole-coupled to each other, but not to the hydrogen nuclei represented by the narrow line. Solid echo experiments confirmed that the clustered and dilute hydrogen phases are separated from each other by at least 500 pm.⁸ Additional echo experiments that exploit the 'quasiquadrupolar' nature of small groups of spin- $\frac{1}{2}$ particles suggested that *isolated* $-\text{SiH}_2$ or $-\text{SiH}_3$ groups are atypical features in a-Si:H, but did not preclude the existence of clustered di- and trihydrides.

Despite the wide range of processing conditions and material properties, all ^1H NMR observations of a-Si:H are remarkably similar. While the relative intensities of the two components in the lineshape vary with deposition conditions and hydrogen content, component shapes and linewidths are essentially invariant. Calculations of the dipolar linewidths

show that certain configurations cannot be present in a-Si:H. For example, hydrogen-passivated mono- and divacancies, containing four and six hydrogen atoms respectively, would yield ^1H NMR linewidths (full width at half-maximum, FWHM) of 90 and 69 kHz, which are far greater than those observed in a-Si:H. Simpler configurations such as $-\text{SiH}_2$, $-\text{SiH}_3$, and $(-\text{SiH}_2)_n$ yield ^1H NMR linewidths less than 20 kHz.¹⁰

2.1.3 Investigations of the Narrow Line

The content of the hydrogen giving rise to the narrow line in a-Si:H never exceeds 12 at.%, despite variations in total hydrogen content between 2 and 32 at.%.^{2,4,5,12} A precise description of the environment of this species has not been established, but it is known that the narrow component of the ^1H NMR spectrum is too broad for the hydrogen to be distributed randomly.⁸⁻¹⁰

The content of hydrogen in this species correlates inversely with the density of paramagnetic spins in a-Si:H. A decrease in ESR-measured spin density with increasing content of hydrogen giving rise to the narrow line has been observed in studies of the deposition of a-Si:H from silane (SiH_4) and from disilane (Si_2H_6) plasmas.¹³ While it is tempting to suggest that the narrow-line hydrogen is 'good hydrogen' and the broad-line hydrogen is 'bad hydrogen', the accumulated results of over 10 years of ^1H NMR experiments show that all a-Si:H films contain the clustered hydrogen phase. The relative amounts of each phase vary as a function of material preparation conditions, but the narrow line contributes at most 60% of the signal intensity in normally deposited films.

2.2 Deuterium Magnetic Resonance

The substitution of deuterium for hydrogen allows one to use the quadrupolar interaction to determine additional information about the hydrogen (deuterium) distribution in a-Si:(D,H). The deuterium magnetic resonance (^2D NMR) spectrum of a-Si:(D,H) is rich in structure. ^2D NMR experiments provide an interesting contrast to ^1H NMR work, since the results, while not contradicting each other, do not seem to coincide directly. Some of these disagreements may be ascribed to chemical differences between hydrogen and deuterium which have manifested themselves in deposition chemistry studies of amorphous silicon.⁶

2.2.1 Typical ^2D NMR Spectra

Typically, three components are observed in ^2D NMR spectra such as those shown in Figure 2. First, there is a quadrupolar doublet that is remarkably invariant with sample preparation conditions, always having a splitting of 66 ± 1 kHz. This doublet is assigned to tightly-bound deuterium in SiD and SiD_2 configurations located in regions of a-Si:(D,H) that are far away from microvoids and have very small bond angle distortions.^{14,15} Second, there is a broad central feature with approximately 27 kHz linewidth that is independent of temperature between 4 and 70 K, but narrows by a factor of five between 70 and 300 K. This

Figure 2 ^2D NMR spectra as a function of annealing temperature (T_A) for an a-Si:D sample, plasma-deposited at 230°C . (Reproduced by permission of the authors and The American Physical Society from V. P. Bork, P. A. Fedders, D. J. Leopold, R. E. Norberg, J. B. Boyce, and J. C. Knights, *Phys. Rev. B*, 1987, **36**, 9351)

broad central line is assigned to weakly-bound deuterium associated with strained bonds in distorted regions near microvoids and to relatively immobile trapped D_2 and HD.¹⁶ The T_1 of ^2D giving rise to this feature is much shorter than that of the T_1 of tightly-bound deuterium.^{14,17} Third, there is a temperature-dependent narrow central feature indicative of trapped molecular D_2 or HD species.¹⁵ This line actually has a two-component shape, as revealed by hole-burning experiments.^{14,17} The narrow (300 Hz) component becomes more narrow with additional annealing, and is probably associated with mobile, dense, molecular deuterium in the microvoids. The broader component narrows from 13 kHz at 18 K to 1 kHz at 300 K, and is probably associated with molecular deuterium adsorbed on microvoid surfaces.

2.2.2 Relationship between ^2D NMR and Infrared Spectroscopy

The stretching force constant for the Si–D bond can be calculated from parameters of the ^2D NMR spectrum.¹⁵ The predicted value is in good agreement with those observed in a-Si:H and a-Si:D using infrared absorption spectroscopy.

2.2.3 Relationship between ^2D NMR and Optoelectronic Quality

The structural information provided by NMR and the electronic properties of a-Si:H have been connected in, at best, an indirect manner. Although NMR studies have certainly contributed to the level of understanding of a-Si:H growth and structure, the connections to electronic applications of the material have not been obvious. Fortunately, this situation is changing. It has been found that the ratio of tightly-bound deuterium (TBD) to molecular deuterium (or HD) in samples of amorphous germanium and amorphous

silicon correlates extremely well with the photoresponse ($\eta\mu\tau$) over five orders of magnitude in $\eta\mu\tau$.¹⁸ Higher values of TBD relative to molecular deuterium correlate with higher photoresponses.

The spin–lattice relaxation of deuterium in a-Si:D and a-Ge:D samples has been described by an error function, indicative of extremely inhomogeneous line broadening.¹⁸ The reciprocal rate parameter in the error function expression correlates well with electronic quality (again measured as the photoresponse, $\eta\mu\tau$). The longer the spin–lattice relaxation time for the ^2D NMR spectral components, the larger the $\eta\mu\tau$ value. These correlations between NMR observables and properties relevant to applications of a-Si:H are extremely significant findings.

2.3 Hydrogen and Deuterium Diffusion in Amorphous Silicon

2.3.1 ^1H NMR Lineshape Measurements

Changes in the ^1H NMR lineshape with annealing, as shown in Figure 3, have been used to infer changes in hydrogen distribution, and to measure the activation energy for hydrogen diffusion.¹⁹

The narrow component linewidth in the ^1H NMR spectra of room-temperature deposited a-Si:H decreases with thermal annealing, presumably because of hydrogen diffusion.¹⁹ It is important to note that since the paramagnetic defect density decreases simultaneously with the diffusion of hydrogen to a less clustered state, this experiment provides direct evidence for the role of hydrogen in defect passivation. This study also determined that the hydrogen that evolves from a-Si:H at temperatures below 400°C comes exclusively from the clustered environments.¹⁹ Another annealing study that used a sample deposited at 330°C did not find this decrease in narrow-component linewidth, nor

Figure 3 ^1H NMR spectra of a-Si:H before (left) and after (right) annealing at 400°C . Top spectra are data fitted by the sum of broad (middle) and narrow (bottom) components. Notice the loss of the broad line and the narrowing of the narrow line with annealing. (Reproduced by permission of the authors and Pergamon Press, from J. A. Reimer, R. W. Vaughan, and J. C. Knights *Solid State Commun.*, 1981, **37**, 161)

was a redistribution of hydrogen from the broad to narrow lines observed.⁸ Both studies find a decrease in total hydrogen content above roughly 400 °C, although the study with the room-temperature material also observed a significant loss of hydrogen at temperatures between 300 and 400 °C.

2.3.2 Activation Energy Measurements

An activation energy for diffusion can be calculated from the narrow-component linewidth data as a function of temperature,¹⁹ from the increase in spin–lattice relaxation rate with temperature,⁸ or from the dipolar spin–lattice relaxation time.²⁰ The calculated values, ranging from 0.2–0.31 eV, are much smaller than values determined by secondary ion mass spectrometry (SIMS) studies and hydrogen-evolution experiments which are typically between 1.0 and 1.5 eV. The significance of the NMR-measured activation energy for diffusion is still not known.⁶

2.3.3 Molecular Hydrogen Evolution

A pronounced increase in trapped molecular hydrogen accompanying the evolution of hydrogen at a-Si:H annealing temperatures above 400 °C has been studied with ¹H NMR. This molecular hydrogen causes the minimum in the spin–lattice relaxation of ¹H in the sample to shift from roughly 54 K to 23 K. A comparison of the molecular hydrogen content measured by spectral intensity²¹ and the H₂ content inferred from analysis of the behavior of T_1 shows that there is much more H₂ in the annealed samples than is predicted from the relaxation experiments. The conclusions are that the microvoids grow with annealing from a radius of approximately 2500 to 5000 pm, and that only those hydrogen molecules on the void surfaces participate in the spin–lattice relaxation process.²²

2.3.4 Microstructure and Hydrogen Diffusion

The relationship between microvoids and molecular hydrogen content has been studied via ¹H T_1 measurements for sputtered a-Si:H prepared with high and low microvoid densities.²³ Hydrogen diffuses very slowly in the high microvoid density sample, and diffuses rapidly in the low microvoid density sample. Although the sample with more microvoids initially has a lower value of T_1 (presumably because of a greater concentration of trapped molecular H₂), the difference in the values of T_1 disappears after moderate annealing drives the molecular hydrogen content of both samples to the same level.

2.3.5 Deuterium Magnetic Resonance Studies of Thermal Annealing Effects

Deuterium magnetic resonance lineshapes for a high quality a-Si:D sample as a function of annealing temperature are shown in Figure 2.¹⁴ Data were acquired at 11 K after anneals at the temperatures shown on the figure. The tightly-bound deuterium (TBD) 66 kHz doublet is clearly observed in all of the spectra, although its intensity diminishes

considerably above 350 °C. The narrow central line, indicative of molecular deuterium, is clearly observed at 350 °C and above. The feature assigned to weakly-bound deuterium (WBD) is a 27 kHz broad central line that is not observed after the 350 °C anneal.¹⁷ This deuterium may account for the observed gas evolution at this annealing temperature. Note that the lineshape is virtually unchanged during the 250 °C anneal (20 °C above the deposition temperature), but that dramatic changes are observed as the annealing temperature exceeds the sample deposition temperature by more than 100 °C.

NMR studies of the annealing behavior of amorphous silicon alloys have been discussed in more detail in an earlier review.⁶

2.4 Multiple Quantum NMR Studies

Multiple quantum NMR has been extremely helpful in understanding the structure of the clustered hydrogen environment, and has provided important information about microstructural changes in a-Si:H caused by doping and annealing.

2.4.1 How Many Hydrogen Atoms are in a Cluster?

¹H NMR experiments have provided overwhelming support for the hydrogenated microvoid picture of the clustered hydrogen environment, with multiple quantum NMR (MQNMR) being especially valuable.^{12,24,25} MQNMR is a multiple pulse technique which examines the behavior of dipole-coupled spin systems (*Multiple Quantum NMR in Solids*). It is actually possible to ‘count’ the number of spins which are involved in a particular isolated system. MQNMR data from spin systems which interact with one another through intercluster couplings can be analyzed to determine the individual cluster sizes. ¹H MQNMR has been used to determine the size of coupled ¹H spin systems in samples of a-Si:H with hydrogen contents from 8–50 at.%, prepared in several laboratories.²⁴ As shown in Figure 4, the sample with the lowest hydrogen content (~8%) displayed an MQNMR response expected for isolated, small (5–7 atoms) clusters of spins. As the hydrogen content of the samples increased, the small intracluster signal persisted, although there was evidence of an increasing amount of intercluster coupling. At the very highest hydrogen content, the isolated cluster signal was not observed. Once again, there is the temptation to assign the broad ¹H NMR line to a hydrogenated divacancy in the silicon lattice but, as has already been discussed, this would be inconsistent with the observed ¹H NMR linewidth. Based on the NMR and MQNMR results, the broad-line hydrogen is most likely to be located at the surfaces of small microstructural features, or microvoids, and these microvoids must be larger than a divacancy.

2.4.2 The Effect of Deposition Conditions on Microstructure

MQNMR has been used to observe the effects of substrate temperature during deposition on the hydrogen microstructure of plasma-deposited a-Si:H.¹² The definition of the hydrogen clusters decreases with substrate temperature, with the highest temperature materials having the

Figure 4 Multiple quantum NMR results for four a-Si:H samples with different hydrogen contents. In this plot, τ is the time that the experimenter has allowed for spins to interact with each other and N is the number that have interacted during this time. The solid line indicates the effective cluster size, $N_c(\tau)$, which is virtually identical to the effective system size, $N(\tau)$, for the 8 at.% hydrogen sample, while $N_c(\tau)$ and $N(\tau)$ are the width parameters of two Gaussians used to fit the data. The value of $N(\tau)$ increases for the 16 and 25 at.% hydrogen samples, while $N_c(\tau)$ remains at roughly six spins. The sample with 50 at. % hydrogen shows no clustering, but behaves as a uniform distribution of spins with N increasing continuously with τ . (Reproduced by permission of the authors and The American Physical Society from J. Baum, K. K. Gleason, A. Pines, A. N. Garroway, and J. A. Reimer, *Phys. Rev. Lett.*, 1986, **56**, 1377)

relatively isolated, 5–7 hydrogen nuclei clusters observed for high-quality films in the earlier study.²⁴ As the substrate temperature decreases, the isolated clusters appear to come closer together, with a larger intercluster coupling observed.

The geometry of the clustered hydrogen in sputtered a-Si:H film has been studied by analysis of MQNMR data (see *Multiple Quantum NMR in Solids*) as shown in Figure 5. The slope of the plotted data represents the dimensionality of the hydrogen atom distribution in the sample. Calcium hydride presents a three-dimensional (bulk) distribution, while diamond powder presents a two-dimensional (surface) distribution. The a-Si:H data on the plot indicate a dimensionality less than two, suggesting that the clustered hydrogen in this undoped sample is distributed on the inner surfaces of columnar voids.²⁵

2.4.3 Effects of Doping on Hydrogen Microstructure

MQNMR studies of hydrogen demonstrate the effects of dopant atoms on the microstructure of a-Si:H. Doping a-Si:H with phosphorus leads to an increase in hydrogen clustering as observed with ^1H NMR¹⁰ and ^1H MQNMR.¹² Boron doping results in a highly segregated hydrogen microstructure.²⁵ This segregation is observed in data similar to those shown in Figure 5, where data from boron-doped a-Si:H have an even smaller slope than the undoped material. This slow growth rate in the number of correlated spins is good

Figure 5 Growth rate of hydrogen multiple quantum coherence in an a-Si:H sample (sample 3) compared with behavior expected for three-dimensional (calcium hydride) and two-dimensional (diamond powder) hydrogen distributions. The slower growth rate in the a-Si:H sample suggests that the hydrogen is in columnar microvoids or a similar environment. (Reproduced by permission of the authors and The American Physical Society from S. Mitra, K. K. Gleason, H. Jia, and J. Shinar, *Phys. Rev. B*, 1993, **48**, 2175)

evidence that the clusters of hydrogen are small and well separated.

2.4.4 Multiple Quantum NMR Studies of Annealing

MQNMR is an excellent monitor of microstructural changes caused by annealing. Samples of a-Si:H, plasma-deposited at temperatures ranging from 113–324 °C, were studied with MQNMR as a function of postdeposition annealing temperature.¹² The annealing study demonstrated that there are massive rearrangements of the hydrogen microstructure at temperatures well below those required to cause hydrogen evolution ($T < 350^\circ\text{C}$). Even high-quality films, deposited at temperatures near 300 °C, show considerable rearrangements of hydrogen during annealing. The ill defined hydrogen microstructure in a-Si:H deposited at low substrate temperatures can be driven toward better defined clusters of hydrogen. However, these low-temperature films do not attain the same structure as the better ones.

2.5 Trapped Molecular Hydrogen

Below 10 K, the ^1H NMR spectrum consists of three components. In addition to the broad Gaussian and narrow Lorentzian absorptions observed at room temperature, a Pake doublet with a splitting of 175 ± 10 kHz is seen in low-temperature spectra.²¹ This feature is ascribed to trapped molecular hydrogen.

The concentration of molecular hydrogen is usually 0.1 at.% or lower for high-quality a-Si:H. Based on this fact, and experimental studies of the broad and narrow components of the ^1H NMR spectrum, it is very unlikely that trapped molecular hydrogen accounts for any significant portion of the narrow Lorentzian component in the

^1H NMR spectrum.²⁶ However, molecular hydrogen does play an important role in a-Si:H NMR studies, since it turns out to provide the predominant spin–lattice relaxation mechanism for bonded hydrogen. NMR of trapped molecular hydrogen and deuterium in a-Si:(D,H) has provided important data for comparison with theories of molecular behavior in porous media and low-temperature phenomena.²⁷ The highly developed level of understanding of the role of trapped molecular hydrogen in ^1H spin–lattice relaxation has been valuable in discovering the structural changes induced in a-Si:(D,H) by thermal annealing. In addition, recent studies have shown that trapped molecular deuterium is a useful probe for observing light-induced defects in a-Si:(D,H).¹⁸

2.5.1 Spin–Lattice Relaxation of Hydrogen in a-Si:H

The characteristic low-temperature minimum in the T_1 of ^1H as illustrated in Figure 6 was initially postulated to arise from the relaxation of hydrogen nuclei by hydrogen-associated disorder modes or ‘tunneling’ modes.²⁸ However, theoretical calculations showed that the number of hydrogen-associated disorder modes that are required to account for the magnitude of the observed ^1H T_1 is too large to be reasonable. This result was later confirmed experimentally.²⁹

It was later proposed that the ^1H in a-Si:H relax via spin diffusion to trapped *ortho*-hydrogen molecules in microvoids. These *ortho*- H_2 serve as spin–lattice relaxation centers.³⁰ The role of spin diffusion in the relaxation process was

shown in a series of experiments that used partially deuterated a-Si:H samples and employed a technique allowing the determination of T_1 in the absence of homonuclear dipolar interactions.³¹ The presence of molecular hydrogen in a-Si:H was confirmed by the detection of the conversion of *ortho*- to *para*-hydrogen at 4.2 K,³² and by the previously mentioned direct observation of a Pake doublet from solid hydrogen in ^1H NMR spectra at temperatures below 10 K.²¹ Deuterium magnetic resonance experiments showed that deuterium molecules trapped in microvoids of a-Si:(D,H) serve as spin–lattice relaxation centers for deuterons.¹⁵

2.5.2 Modeling the Spin–Lattice Relaxation of Hydrogen

Theoretical calculations have been helpful in understanding the relaxation process in intrinsic (undoped) a-Si:H.^{27,33} A ‘spin diffusion bottleneck’ term is required to model accurately the T_1 versus temperature observations as shown in Figure 6.^{27,30} This term represents the transfer of magnetization from bonded hydrogen in the bulk of a-Si:H to the microvoid regions (where trapped molecular hydrogen resides) by spin diffusion. Note that the bottleneck term is most significant near the T_1 minimum, and is not important in room-temperature measurements of T_1 .

Hydrogen in doped a-Si:H relaxes via a slightly different mechanism. For example, spin–lattice relaxation measurements versus temperature in boron-doped a-Si:H do not show a well-defined minimum. The boron in the material affects the microstructure in such a way that the importance of the spin diffusion bottleneck term is significantly enhanced.³⁴

Condensed molecular hydrogen has been observed in a-Si:H by a variety of methods.^{21,33} However, the temperature-dependence of the ^1H T_1 in a-Si:H seems to indicate a coupling to *dilute ortho*- H_2 molecules. The spin–lattice relaxation of condensed H_2 does not show the characteristic minimum between 25–55 K, magnetic field dependence, or relaxation rates that are typical of ^1H in a-Si:H that are presumably relaxed by coupling to trapped molecular hydrogen.³³ This apparent paradox may be resolved by considering that the *ortho*- H_2 molecules responsible for relaxation of bonded hydrogen are adsorbed on the internal surfaces of microvoids. These molecules are then ‘effectively dilute’, because their intermolecular electric quadrupole–quadrupole interactions are quenched by their interaction with the silicon surface.²⁷ This prevents the adsorbed *ortho*- H_2 from interacting with the bulk, condensed H_2 in the microvoid. This model can also account for the observation that the concentrations of molecular hydrogen determined from spectral areas of the Pake doublet are always larger than those inferred from ^1H T_1 measurements. Only that fraction of the trapped hydrogen molecules adsorbed on the void surfaces in a-Si:H are relaxation centers for hydrogen atoms bonded to silicon.²¹

2.5.3 Trapped Molecular Hydrogen and Microvoid Structure

A particularly interesting conclusion of these studies, which is complemented by recent studies of microvoids and hydrogen clustering in a-Si:H, is that the trapped molecules

Figure 6 Data which clearly show the temperature minimum in ^1H T_1 . Data were acquired at 42.3 MHz (solid dots) and 12.3 MHz (triangles). The solid and dot-dashed lines are fits to the data using a relaxation model that incorporates the effects of spin diffusion. The dashed lines are model predictions without considering spin diffusion. The horizontal line marks the spin diffusion-limited T_1 minimum of 0.16 s. (Reproduced by permission of the authors and The American Physical Society from M. S. Conradi and R. E. Norberg, *Phys. Rev. B*, 1981, **24**, 2285)

reside in well-defined sites.³² The spin–lattice relaxation behavior of several a-Si:H samples was modeled with various assumptions made about the symmetry of the electric field gradient (EFG) at the *ortho*-H₂ molecule. It was found that the EFG has, at most, axial symmetry and this symmetry is only observed in certain samples. The sites with axial symmetry are *ortho*-H₂ located in small voids of ~ 500 pm diameter, and the sites with no (or low) symmetry are larger voids in which the *ortho*-H₂ are adsorbed at the surface.²⁷

2.5.4 ²D NMR Observation of Light-Induced Defects

²D NMR spectra have been observed before and after light-soaking a-Si:D samples.¹⁸ All of the features discussed above for typical ²D spectra are observed in both spectra, with the tightly-bound deuterium doublet and the narrow central line unchanged. However, the broad central component does change. Approximately 0.5% of the deuterium atoms in the sample are affected by light exposure, most probably because they are in the vicinity of a light-induced paramagnetic defect. These deuterium atoms are those that are either nanovoid-trapped HD and D₂, or weakly-bound deuterium involved in distorted silicon–deuterium bonds. Based on the change in paramagnetic centers measured with electron spin resonance, roughly 500 deuterium atoms are affected by each light-induced defect.

3 LATTICE STRUCTURE (²⁹Si, ¹³C)

The concepts of disorder and randomness are common themes in discussions of amorphous materials. NMR studies of the silicon network itself in a-Si:H have been used to learn more about the order that does exist amidst the long-range aperiodicity. NMR studies of alloyant atoms in amorphous hydrogenated silicon alloys have been helpful in studying the structural differences between a-Si:H and related alloys.³

3.1 ²⁹Si NMR of a-Si:H

3.1.1 Cross-Polarization Experiments

The low natural abundance of ²⁹Si (4.7%), relatively low resonance frequency, and long spin–lattice relaxation times make ²⁹Si NMR experiments difficult.⁶ Cross polarization techniques are the most common NMR experiments used to study silicon in a-Si:H because of the ²⁹Si sensitivity enhancement, and because signal averaging is dependent only on the ¹H T₁^{35–37} (see *Cross Polarization in Solids*).

The results of initial ²⁹Si NMR studies of plasma-deposited a-Si:H films were disappointing.³⁷ Cross-polarization experiments with high-power hydrogen decoupling during data acquisition, with and without magic angle spinning, yielded extremely broad lines whose width far exceeded the chemical shift range expected for silicon–hydrogen environments. The modest narrowing induced by magic angle spinning is illustrated in Figure 7. These observations suggested that neither the dipolar interaction nor chemical shift anisotropy was

Figure 7 ²⁹Si NMR spectra for a-Si:H acquired with (bottom) and without (top) 2.2 kHz magic angle spinning (MAS). Although the spectrum narrows with MAS, the narrowing is much less than expected if chemical shift anisotropy were responsible for the line broadening. (Reproduced by permission of the authors and The American Institute of Physics from J. A. Reimer, P. Dubois Murphy, B. C. Gerstein, and J. C. Knights, *J. Chem. Phys.*, 1981, **74**, 1501)

responsible for the ²⁹Si NMR linewidth. The insensitivity of linewidth to magic angle spinning, and the elimination of other line-broadening interactions as factors, led to the conclusion that the silicon NMR line is inhomogeneously broadened by the variation in silicon bonding environments in a-Si:H (see *Magic Angle Spinning*).

The large residual linewidths were predicted using a model of a-Si which included large charge-density fluctuations in the lattice, leading to large chemical shift dispersions. The results of the calculations were in excellent agreement with the observed ²⁹Si linewidths of sputtered a-Si:H samples.³⁶

There is a correlation between the average chemical shift of ²⁹Si and the fraction of the hydrogen NMR signal represented by the narrow line (see Section 2).³⁵ This change in the ²⁹Si chemical shift also correlates well with the ‘amount of microstructure’ parameter derived from IR measurements, suggesting that the local environment beyond nearest-neighbor bonding can be inferred from ²⁹Si NMR measurements.³⁸

Variations on the cross polarization pulse sequence have been used to probe the relationship between silicon and hydrogen, and to resolve the overlapping signals from environments with different hydrogenation.³⁹ In the most straightforward experiment, it was confirmed that molecular hydrogen was a negligible contributor to the intensity of the ¹H NMR narrow line, and that the broad- and narrow-line hydrogen in a-Si:H are spatially separated. This experiment and a related study using cross depolarization have been discussed in detail in an earlier review.⁶

The dynamic nuclear polarization (DNP) technique has been used to enhance ²⁹Si NMR signals, and to study selectively regions of samples near paramagnetic defects in nonhydrogenated a-Si.⁴⁰ DNP is a double resonance experiment that uses the unpaired electron as the source of

magnetization to transfer to the ^{29}Si (see *Dynamic Nuclear Polarization and High-Resolution NMR of Solids*).

3.1.2 Free Induction Decay Measurements

Recently, ^{29}Si has been studied in a-Si:H^{38,41} and a-Si⁴² by acquiring free induction decays. This experiment allows the observation of both hydrogenated and nonhydrogenated silicon atoms, and the measurement of relaxation time constants. Although it is the most basic pulsed NMR technique, this experiment is challenging because of the long spin–lattice relaxation times of ^{29}Si in a-Si:H. Spin–lattice relaxation times were determined to be on the order of 100 min for high-quality samples. These long relaxation times can be modeled by a paramagnetic center relaxation mechanism, and results for samples prepared under different conditions can be interpreted in terms of the distribution of paramagnetic defects in the material. High-quality samples show a single relaxation time (T_1), while samples of lower quality (with demonstrably worse electronic properties) show at least two distinct relaxation times. These observations suggest that paramagnetic dangling-bond defects are distributed randomly in high-quality a-Si:H, whereas in lower grade a-Si:H the defects tend to cluster. This interpretation is reminiscent of just about every other measurement of a-Si:H microstructure, and provides yet another bit of support for the view that these materials are heterogeneous rather than random.⁴¹

The effects of thermal annealing on the local order of the silicon lattice in sputtered, nonhydrogenated a-Si have been studied with silicon NMR and correlated with Raman spectroscopy measurements.⁴² There is a gradual decrease in ^{29}Si NMR linewidth with annealing temperature above 400 °C, while the line position is essentially constant until the temperature exceeds 600 °C. At this point the sample begins to crystallize, and a narrow feature typical of crystalline silicon appears in the spectra at -79.9 ppm. Note that none of these changes is due to hydrogen diffusion, since these samples are not hydrogenated. Rather, these changes reflect rearrangements of the silicon lattice with concomitant changes in the short-range order.

3.2 ^{13}C NMR of Amorphous Silicon Carbide (a-SiC:H)

NMR studies of ‘backbone’ atoms in amorphous silicon alloys have been reviewed previously.³ An example of these studies is provided by the spectra depicted in Figure 8. Carbon-13 NMR spectra of a-SiC:H were acquired as free induction decays with and without high-power proton decoupling. Two major pieces of information were obtained from the data: carbon exists in both sp^3 and sp^2 configurations in a-SiC:H, and the sp^2 carbons are not hydrogenated.⁴³ Prior to this work, it was common to assume that carbon was incorporated into the a-Si:H lattice substitutionally, and behaved similarly to silicon.

4 DOPANT ATOMS (^{11}B , ^{31}P)

Phosphorus and boron are the most commonly used dopants in a-Si:H. Phosphorus doping results in an n-type,

Figure 8 Carbon-13 NMR spectra of three a-SiC:H samples. ‘On’ and ‘Off’ indicate proton decoupling and no proton decoupling, respectively. The left peak is sp^2 carbon; the right peak is sp^3 carbon. Notice the negligible change in the sp^2 peak with proton decoupling. The disappearance of the sp^3 peak in the spectra without decoupling indicates that the sp^3 carbon environments are hydrogenated. (Reproduced by permission of the authors and The American Physical Society from M. A. Petrich, K. K. Gleason, and J. A. Reimer, *Phys. Rev. B*, 1987, **36**, 9722)

or electron rich, material, while boron doping leads to a p-type, or electron deficient (hole-rich) material. Phosphorus doping provides additional electron energy states near the conduction band; boron doping provides additional states near the valence band.¹ These nuclei have been observed in simple NMR experiments,^{44–48} their relaxation behavior has been studied,^{44,47,48} and their spatial relationship to hydrogen has been probed with double-resonance experiments.⁴⁴

4.1 ^{31}P NMR

The doping efficiency of amorphous silicon is quite low compared with crystalline silicon. In order to be an active dopant, phosphorus atoms must be bonded in fourfold-coordinated configurations. However, several ^{31}P NMR studies have shown that the large majority of phosphorus atoms in a-Si:H are in threefold-coordinated bonding configurations.^{44,48,49} Spectra were determined to consist of two overlapping resonance bands by acquiring ^{31}P NMR data with both free induction decay and spin echo measurements. The two resonances have been assigned to threefold- and fourfold-coordinated phosphorus by comparison with phosphorus reference compounds.⁴⁸

The spin–spin relaxation time (T_2) for threefold-coordinated phosphorus in a-Si:H(P) can be modeled by considering only the homonuclear dipole coupling. The interaction between hydrogen and phosphorus does not have to be included in computations of the dipolar linewidths, which is consistent with the experimental observation that hydrogen contributes negligibly to ^{31}P spin–spin relaxation.⁴⁸ Samples prepared with different hydrogen contents, or with the hydrogen removed by thermal annealing, have virtually identical ^{31}P spin–spin relaxation times ($T_2 = 1.0\text{--}1.5\text{ ms}$). Experiments using heteronuclear dipolar decoupling also show no appreciable coupling between hydrogen and phosphorus.^{46,47} It is also interesting to note that, below 2 at.% the phosphorus concentration has little effect on the magnitude of T_2 of ^{31}P . Samples with 2% and 0.5% phosphorus have essentially the same values of T_2 leading to the conclusion that phosphorus does not distribute homogeneously in a-Si:H(P) but is located in regions of constant local concentration.⁴⁴ In samples with higher phosphorus concentrations, local concentrations of phosphorus will increase, leading to shorter values, of T_2 . A sample with 21 at.% phosphorus, for example, had $T_2 = 460\text{ }\mu\text{s}$.⁴⁷

The fourfold-coordinated phosphorus configuration has only been observed in two studies,^{48,49} one of which showed the light-induced conversion of fourfold-coordinated sites to threefold-coordinated sites. That experiment is described below. Other studies which did not detect evidence for the fourfold-coordinated sites probably involved light-soaked materials,^{44,46,47} as has been suggested by one of the authors.⁴⁴ Spin–spin relaxation of the fourfold-coordinated phosphorus is considerably different from the threefold-coordinated phosphorus. The relaxation is much faster ($T_2 < 0.2\text{ ms}$), and coupling to hydrogen is an important relaxation mechanism. In fact, these fourfold-coordinated phosphorus atoms must be located near the environment of the clustered hydrogen or else the coupling to hydrogen would be an ineffective mechanism for relaxation.^{44,48} The exact relationship between the phosphorus and hydrogen environments is not known, but it is estimated that the fourfold-coordinated phosphorus sites are located within 500 pm of the hydrogenated microvoids, and may actually be at the surface of the voids.⁴⁸

The phosphorus spin–lattice relaxation time (T_1) varies from several minutes to less than 1 min depending upon sample preparation conditions and phosphorus content. Compensated samples [a-Si:H(P,B)] have much longer ^{31}P T_1 values (18.3 min) than similarly prepared singly-doped material (1.5 min).⁴⁴ The relaxation mechanism provides additional information about the sample. The values of T_1 are so large that it is unlikely that interaction of phosphorus nuclei with conduction electrons (Knight shift) is important. Also, the large shifts in resonance frequency typical of Knight shifts are not observed⁴⁹ (see *Internal Spin Interactions and Rotations in Solids*).

4.1.1 Observation of Metastable Bonding Configurations of ^{31}P

The effects of light exposure on the bonding configurations of phosphorus in a-Si:H were dramatically revealed by ^{31}P NMR as shown in Figure 9.⁴⁹ These studies showed that as deposited, phosphorus-doped a-Si:H contains only

Figure 9 ^{31}P NMR spectra from n-type a-Si:H as deposited (top), after annealing in the dark (middle), and then after light soaking (bottom). Because the as deposited sample can be assumed to be light-soaked, these spectra show the metastable formation of fourfold coordinated phosphorus bonding sites. (Reproduced by permission of the authors and The American Physical Society from M. J. McCarthy and J. A. Reimer, *Phys. Rev. B*, 1987, **36**, 4525)

threefold-coordinated phosphorus, with a single broad resonance observed at 170 ppm (relative to phosphoric acid). Exposing this material to light had no effect on the phosphorus bonding. However, annealing the samples at 100 °C in the dark for 2 h induced a transformation of 20% of the threefold-coordinated phosphorus to the fourfold-coordinated form, as indicated by overlapping broad resonances at 80 and 170 ppm. Subsequent exposure to light reversed the effect of annealing, and the sample again contained only threefold-coordinated phosphorus. All of these changes were well within the sensitivity of the spectrometer used. This experiment was the first to elucidate the structural changes involved in a metastable response of a-Si:H to light exposure and thermal annealing.

The location of the metastable phosphorus relative to hydrogen was determined by using the Hahn spin echo technique. When a delay of 250 μs was used between the initial pulse and the echo pulse, the observed lineshape only showed threefold-coordinated phosphorus. This result suggested that the fourfold-coordinated phosphorus nuclei are in close proximity to clustered hydrogen nuclei that promote rapid relaxation of the phosphorus magnetization.⁴⁹

4.2 ^{11}B NMR

NMR studies of ^{11}B in a-Si:H have provided additional information about why doping efficiencies are so poor.^{34,44,45,50} Spin echo linewidths ($1/T_2^*$) can be used to determine nuclear quadrupole coupling constants for ^{11}B , which are extremely sensitive to local bonding coordination. In samples ranging from 0.7–10 at.% boron, the boron atoms are overwhelmingly in threefold configurations. There are no detectable fourfold-coordinated boron atoms.⁵⁰ Films with the lowest boron levels contain singly or doubly hydrogenated boron, but when boron concentrations are large the films also contain boron atoms which are bonded to three silicon atoms. Measurements of spin-spin relaxation (T_2) via the spin echo technique demonstrate that neither B–B bonds nor B_2H_6 molecules exist in greater than trace amounts in boron-doped a-Si:H. The T_2 values are too large. However, the T_2 values are too small to support a picture of randomly distributed boron atoms even in the 0.7 at.% boron materials. There are significant variations in the local concentration of boron atoms, but these variations do not include boron atoms directly bonded to each other.⁴⁵

In compensated materials [a-Si:H(P,B)] approximately 25% of the boron atoms bond in a fourfold-coordinated fashion.⁴⁴ These are identified by their very narrow linewidths ($<2\text{ kHz}$) which are comparable to the observed ^{11}B NMR linewidths in p-type crystalline silicon. Despite this high fraction of boron in the supposedly desired fourfold-coordinated environment, the doping efficiency in these materials is still quite low. As described below, it is known that the boron–phosphorus clustering occurs to a high degree in compensated a-Si:H, so these fourfold-coordinated boron atoms are most likely in BPSi_3 units or similar configurations. The presence of boron and phosphorus in close proximity obviates the doping effect from either atom.

4.3 Spin Echo Double Resonance Experiments

Spin echo double resonance (SEDOR) experiments have been used to measure the distances between phosphorus and boron atoms in compensated a-Si:H, and to measure the distance between hydrogen atoms and either phosphorus or boron in both compensated and singly-doped films.⁴⁴ The SEDOR pulse sequence consists of a standard spin echo experiment (e.g. 90° , τ , 180° , τ , echo) with an additional 180° pulse applied at a different resonance frequency simultaneously with the 180° pulse in the sequence. The additional pulse flips the heteronuclear spins, changing the local field at the observed nuclei. Since the local field depends upon the distance between the two nuclei, comparisons of the spin echo with and without the ‘extra’ pulse provide the information needed to calculate the distance between two different nuclei, or to establish the parameters of a distribution of nuclei around the observed nucleus.

The SEDOR data shown in Figure 10 demonstrate the clustering of boron and phosphorus that occurs in compensated a-Si:H films. The figure also shows the results of calculations for situations where the boron and phosphorus are totally clustered, arranged completely at random, and when they are arranged in a CsCl-type lattice. None of these situations is representative of the real situation. The data are fitted by two

Figure 10 Boron–phosphorus SEDOR decay data for compensated a-Si:H. The sample contains 2 at.% B and 2 at.% P. Three models fail to explain the observed data. Curve A comes from assuming that each B is bonded to a P, curve B is based on a random distribution of B–P pairings, and curve C is based on B and P being arranged on a CsCl-type lattice. (Reproduced by permission of the authors and The American Physical Society from J. B. Boyce and S. E. Ready, *Phys. Rev. B*, 1988, **38**, 11 008)

Gaussian curves whose parameters indicate that B–P units with a bond length of 210 pm account for roughly 40% of the boron in the film, and that the other 60% of the boron atoms have phosphorus atoms roughly 380 pm away. In this film, with 2 at.% boron and 2 at.% phosphorus, a random distribution of dopants would have 8% of the boron atoms bonded in B–P units. The observed 40% is far in excess of the random value, showing that boron and phosphorus have a strong chemical affinity for each other in a-Si:H. This helps to explain the poor doping efficiency of compensated materials.⁴⁴

1 INTRODUCTION

The physicochemical diversity of multiphase and multicomponent systems inevitably poses a great many difficulties to the experimentalist. NMR allows investigation of these systems by a combination of direct structural information, obtained through lineshape analysis and chemical shift data, and indirect information from dynamic measurements of spin relaxation and diffusion. In this article we focus on a specific subset, i.e. dispersions of colloidal particles in fluids. In particular, we describe how NMR methods can be used to investigate the interfacial properties of the system under study and help to shed light on the structure of the adsorbed layer (e.g. solvent, polymer, etc.) at the particle surface. Colloidal dispersions are of considerable importance industrially and are also of intrinsic scientific interest themselves. Specific examples of their use include such diverse applications as additives for toothpaste, engine oils, paints, and cements, to name but a few. These systems generally consist of solid particles dispersed in a liquid phase (e.g. polystyrene latex, silica sol). Colloidal systems such as foams (gas dispersed in a liquid phase) and aerosols (liquid or solid dispersed in a gas phase) will not be discussed. Polymer–surfactant interactions and emulsions (one liquid phase dispersed in another liquid phase) are briefly discussed; however, a detailed review of these systems will not be presented. For more specific references the reader is referred to other articles within the Encyclopedia dealing with these subject areas.

The present article is divided into sections focusing on the interactions of the colloidal particle with either the dispersion medium itself, or with other small molecules, surfactants, polymers, or proteins also present in the dispersion medium. It is not intended that the current article provide an extensive review, rather we seek to highlight, by example, a small number of the numerous and varied applications of NMR within this area.

2 SPECIAL CONSIDERATIONS

NMR spectroscopy, by virtue of its operating frequency and the limitations imposed by the Boltzmann distribution,

is not a sensitive spectroscopic technique, though major advances (albeit in rather specific situations) such as the PASADENA (*para*-hydrogen and synthesis allow dramatically enhanced nuclear alignment)^{1,2} experiment seek to alleviate these problems. Nevertheless, at high field and with suitable sample volumes, it is relatively easy to obtain spectra of interfacial species specifically. Several factors determine this sensitivity, and as these are different from the more usual NMR considerations we will discuss them in some detail.

2.1 Surface Area

In any interfacial study of adsorbed species, two important considerations are the adsorption isotherm and the total surface area available for adsorption. For a nonaggregated substrate consisting of monodisperse spherical particles at a given volume fraction, the surface area is inversely proportional to the particle radius. Hence, particles in the colloid size regime (ca. 10–500 nm) are ideally suited to provide a well-defined system with a high surface area per gram of substrate. A high volume fraction of the substrate is desirable in order to improve the signal-to-noise ratio of the NMR spectrum. However, the consequences of interparticle interactions at these high concentrations and their effects on the structure and stability of the colloidal system must be considered during sample preparation.

2.2 Stability

The stability of the dispersion is closely related to its surface area. Aggregation/flocculation of the colloidal particles can dramatically reduce the available area to adsorbing species such as solvent or polymer. For charged particles in aqueous dispersions, this problem can often be neglected during the timescale of an NMR experiment, though settling might be problematical if the density of the particles is considerably greater than that of the surrounding dispersion medium. In nonaqueous dispersions it is essential that the particles are stabilized in some fashion since a charge stabilization mechanism is usually inoperative in the low dielectric constant media used in these formulations. In these cases, stabilization may be achieved by matching the Hamaker constant³ of the particle with that of the dispersion medium, or by adding a suitable polymeric stabilizer or surfactant.³

The reduction in surface area is not the only problem brought about by destabilization (i.e. aggregation/flocculation) of the colloidal system, since the adsorbed surface layer can become compressed, desorbed, or otherwise modified by the (now) high degree of particle packing. This effect is particularly noticeable with measurements of the linewidths of the adsorbed species, since the surface species may now have a considerably reduced mobility dependent on the exact nature of the aggregates formed.⁴

2.3 Exchange

In many colloidal dispersions the continuous phase (e.g. water) will be in dynamic exchange between the bulk and the surface. In the fast exchange limit the average relaxation

rate of the solvent will depend on the accessible surface area and its residence time/interaction mechanism at the particle surface. The residence time of the solvent will also be sensitive to competitive solutes such as surfactants and polymers. Examples of these measurements will be given in later sections. In cases where the lifetime of the adsorbed species is very long or where the exchange rate is limited by strong surface interactions or physical barriers, then complex exchange equations must be employed.⁵ Direct observation of spectra from surface species that are not in fast exchange can also be used to probe both the surface orientation and the dynamics of the adsorbed species.

2.4 Susceptibility/Homogeneity/Anisotropy

In any multiphase system there will be abrupt changes in magnetic susceptibility upon passing from one phase into another. This may have severe consequences for conventional high-resolution NMR studies in terms of resolving and interpreting the chemical shifts or (in solid state studies) chemical shift tensors. In such systems, however, these exchange-broadened resonance lines may be the only route to obtain any useful information. In extreme cases it may be impossible to obtain spectra from the surface layers.

The anisotropic nature of the mobility of the adsorbed species must also be considered. If such motion occurs, detailed quadrupolar relaxation measurements can be used rather effectively to probe the dynamics of the surface layer. In many systems a lack of mobility of the surface-adsorbed phase means that it is impossible to obtain spectra from that phase directly using conventional high-resolution spectrometers, and thus solid state techniques are required. However, both methods have associated problems, such as the centrifugation of the colloidal dispersion during magic angle spinning and the shortening of rotating frame relaxation times on adsorption. The resulting consequence is that some cross polarization experiments become difficult.

2.5 Techniques

In colloidal dispersions the full panoply of NMR methods can, in principle, be used to some advantage though, generally, the more conventional methods of relaxation analysis, diffusion and high-resolution/solid state chemical shift measurements have been employed most extensively. Other approaches such as imaging have a role to play, although by their very nature colloidal particles are too small for the spatial resolution currently possible, and thus a detailed structural analysis is not possible. Techniques that operate on the molecular length scale (e.g. relaxation) are often more appropriate in such cases. Combined electrophoresis and NMR self-diffusion techniques may have significant roles to play, though at present these methods are not widely available (see *Electrophoretic NMR*). One interesting facet of the study of particulate colloidal dispersions by NMR is the spectrum that arises from the substrate itself. The methods and techniques that can be used to study the substrate directly rely on dipolar decoupling (discussed extensively in other articles within this Encyclopedia); however, below a certain size (ca. 1–2 nm) the rotational diffusion of the particle itself may be sufficient to narrow the resonance line.

3 INTERACTIONS OF SMALL MOLECULES WITH COLLOIDAL PARTICLES

As mentioned before, the average relaxation time (rate) of solvent molecules in colloidal dispersions consisting of particulate matter is a source of direct information on the particle structure and affinity of the surface for the solvent molecule. Figure 1 shows a set of water spin–spin relaxation

Figure 1 Normalized specific solvent (water) relaxation rates for hydrophobic and hydrophilic surfaces as a function of surface area: (■) alumina; (□) silica; (●) positive polystyrene latex; (○) negative polystyrene latex

data expressed as a specific relaxation rate, $R_{2sp} = (R_{2d} - R_{2s})/R_{2s}$, where d relates to the overall colloidal dispersion and s to the pure solvent. Several interesting features can be seen in these data. Firstly, data taken from different sized particles of the same substrate (e.g. silica sols) fall on the same line, demonstrating that NMR can be used to monitor the total available surface area in a dispersion in situ, which is not straightforward to achieve by other means. Secondly, and possibly of more general interest, is the gradient and nature of each line: the straight line dependencies indicate that the samples satisfy the fast exchange limit and the gradients are related to the relative affinity of the particles, both in a magnetic and chemical sense, for the solvent. Comparison of the silica and alumina data show a stronger solvent–surface interaction for the latter. Care must, however, be taken when interpreting these data since paramagnetic impurities may be present in the sols and these may artificially (in this case) enhance the relaxation rate. Comparing the two polystyrene latex samples with the inorganic sols demonstrates the more hydrophobic nature of the polymer particles and, in the case of the negatively charged polystyrene latex, its lower surface charge density. In mixed particulate dispersions the specific relaxation rates are additive, and these simple measurements can be used to monitor heteroflocculation and competitive solvation. For example, competitive solvation has been investigated in the system comprising water, dimethylformamide, and silica, using relaxation rate measurements.⁶ More detailed studies of the structure of the solvent layer (water) can be made using ¹⁷O and ²H relaxation which are sensitive to changes in intramolecular motion.⁷ These studies make it possible to distinguish effects such as proton exchange with surface hydroxyl groups and the role of anisotropic surface mobility

Figure 2 Variable temperature 75 MHz ^{13}C NMR spectra of CO adsorbed on colloidal palladium (ca. 1% in methylcyclohexane) at: (a) 220 K (364 transients); (b) 298 K (8000 transients); (c) 333 K (50 000 transients). Spectra are proton decoupled

of adsorbed solvent. The extension of these methods to other colloidal systems (micelles, vesicles, microemulsions, etc.) is well established,⁸ as is the use of paramagnetic probes as relaxation-rate enhancers.⁹

Several recent studies have focused on the adsorption of small molecules (as distinct from solvent) from solution onto colloidal particles. One interesting example is the use of ^{13}C NMR to follow the adsorption of carbon monoxide onto colloidal platinum, a system of commercial interest in the automotive industry.¹⁰

Figure 3 ^{195}Pt NMR spectrum obtained from platinum colloid after bubbling with CO gas for 30 min. Resonance at 42.460 MHz [full width at half maximum (FWHM) of 8 kHz] due to platinum surface atoms bound to CO

Figure 2 shows a 75 MHz ^{13}C spectrum of 2 nm diameter particles stabilized by poly(vinyl pyrrolidone) dispersed in methylcyclohexane. A standard high-resolution spectrometer was used to obtain the data. The adsorbed CO resonance occurs at 200 ppm but shows no Knight shift. This latter observation was explained by the particle being of insufficient size to have metallic character. In a later paper,¹¹ the authors presented indirect evidence which indicated that larger particles did indeed show such a shift. The effects of exchange with CO in the bulk, of course, must be allowed for when interpreting these chemical shifts. The adsorption of CO onto colloidal platinum¹² can also be seen by direct observation of the ^{195}Pt spectrum, as shown in Figure 3 where a shoulder appears to the left of the main peak. These two examples indicate the complementary nature of multinuclear MR in surface studies of this type.

4 INTERACTION OF SURFACTANTS WITH COLLOIDAL PARTICLES

There are two approaches to monitoring the structure of adsorbed surfactants in colloidal dispersions. Firstly, if the added surfactant alters the exchange rate of the solvent, then a measure of the exchange-averaged relaxation rate of the solvent will give information on the surfactant, provided that any bulk solvent-surfactant interaction is taken into account. One system where this approach has proven itself useful is in the study of the adsorption of nonionic surfactants onto silica.¹³ Figure 4(a) shows the solvent relaxation enhancement $R_{2sp} = (R_{2d} - R_{2p})/R_{2p}$ (where d represents the total colloidal dispersion, and p is a 'bare' particle dispersion at the same solids concentration) for the nonionic, dodecylpoly(ethylene oxide) surfactant C_{12}EO_6 as a function of the solution equilibrium concentration. The results show a sharp increase in the solvent relaxation rate enhancement at a solution concentration of ca. 0.8 mmol dm^{-3} [approximately equal to the critical micelle concentration (CMC) of the surfactant] which then becomes independent of solution concentration. These changes follow the adsorption isotherm rather closely. In the 'plateau' region of the adsorption isotherm, C_{12}EO_6 forms a bilayer. In Figure 4(b) we show data for two other poly(ethylene oxides): an EO_{22} homopolymer and a $\text{C}_{12}\text{EO}_{25}$ copolymer. In the latter case the solvent relaxation rate enhancement is slightly lower than that for C_{12}EO_6 , and the sharp increase is slightly less pronounced. Again, the changes follow the adsorption isotherm, this time forming surface aggregates (or a 'broken bilayer') at the silica surface. The single layer formed by the poly(ethylene oxide) homopolymer E_{22} shows only a very weak relaxation rate enhancement, suggesting that the bilayer formed by C_{12}EO_6 and the surface aggregates formed by $\text{C}_{12}\text{EO}_{25}$ immobilize much more water at the silica-water interface.

The second approach is to study the adsorbed layer directly with a quadrupolar nucleus such as ^2H . This has been carried out in a study of the adsorption of sodium 4-(1'-heptylnonyl)benzenesulfonate (SHBS) (a double-tailed surfactant) at pH 4 onto γ -alumina.¹⁴ Figure 5 shows a series of spectra obtained at an operating frequency of 30.7 MHz using a quadrupolar echo sequence and 20 000 transients. Data at two coverages are shown, together with the spectra for

Figure 4 Normalized specific solvent relaxation rates of surfactant/water/silica systems as a function of surfactant equilibrium concentration. (a) $C_{12}(EO)_6$. (b) $C_{12}(EO)_{25}$ (Δ) and $(EO)_{22}$ ($\circ$)

Figure 5 ²H spectra of SHBS-*d*₄ at 25 °C: (a) adsorbed on γ -alumina at low surface coverage; (b) adsorbed at high coverage; (c) in a 2% (w/w) water solution; (d) in liquid crystals with water

the same molecule in solution and in a liquid crystal. At low surface coverage (a) the spectrum consists of a single broad line [in comparison with the molecule in a 2% (w/w) solution (c)]. Given that a proportion of the signal must come from free surfactant the observed spectrum (a) must be exchange broadened. The absence of any quadrupolar splitting suggests

that the sample motion is not completely anisotropic. At high coverage (b), a distinct Pake doublet and a sharp central line appear. This can be compared with (d) which shows the same surfactant dissolved in a liquid crystal where the motion is very anisotropic. According to the authors, these strongly suggest that there are now two environments: an inner ordered layer, and a more mobile outer layer which is in fast exchange with the bulk. It is also likely that there will be slow exchange between the two domains. In other words, the authors suggest the formation of a surfactant bilayer at the alumina–water interface. They were unable, however, to indicate more precisely the exact nature of this bilayer. The spectral detail that results from this study again indicates the complementary nature of the two approaches.

An elegant technique developed by Macdonald et al.^{15–18} uses the quadrupolar splitting observed in the ²H spectra of an adsorbed surfactant [deuterium-labeled hexadecylphosphocholine (HDPC)] to monitor the surface charge of the substrate or changes in the surface charge upon adsorption of another species, say, a polyelectrolyte. If an external force alters the conformation of HPDC then a change in the quadrupolar splitting in its ²H NMR spectrum will be observed. Clearly though, some assumptions have to be made regarding the structure of the mixed layer if species other than HPDC are present at the particle surface. Nevertheless, this technique offers great potential for studies of surface electrostatics in colloid science.

5 INTERACTION OF POLYMERS WITH COLLOIDAL PARTICLES

Polymers are used in a multitude of colloidal formulations to modify the properties of both the substrate and the dispersion medium. The addition of polymer can increase the viscosity of the dispersion medium and hence increase the stability to settling. Alternatively, they can be added to promote or discourage stabilization via adsorption onto the colloidal particles. The properties that the adsorbing polymers impart to the substrate are directly related to the structure and dynamics of the adsorbed polymer layer. These relationships have been discussed in detail in a recent text.¹⁹ The NMR techniques available to monitor these adsorbed, polymeric structures are solvent relaxation and diffusion, adsorbed polymer relaxation, multiple pulse, and cross polarization; each of these will be discussed briefly.

The first observation of polymer adsorption using NMR found that the spectrum arising from the adsorbed layer disappeared at low polymer coverages.²⁰ This was interpreted as the adsorbed chains lying flat at the interfacial plane and being sufficiently dipolar broadened that they were not visible in a normal high-resolution spectrum. This led to the idea that, by making quantitative measurements of signal intensity, and knowing the adsorption isotherm, it should be possible to determine the fraction of polymer segments immobilized at the interface (p) as a function of the adsorbed amount.²¹ The data derived from multiple pulse experiments of both solid and liquid echoes are shown in Figure 6. In this instance, p is defined as the height of the solid echo divided by the height of the solid and liquid echoes combined. The results show that as the surface occupancy increases the chains become more extended and a smaller proportion of

Figure 6 (a) Scheutjens–Fleer lattice model calculation for the polymer bound fraction as a function of adsorbed amount. (b) Experimental data as a function of surface coverage: (●) NMR; (■) ESR

the segments is immobilized. For comparison, ESR data on the same system are shown, as is a theoretical lattice model calculation based on the Scheutjens–Fleer theory of polymer adsorption.¹⁹ The agreement between the two experimental methods is rather pleasing and shows the consistency in using a mobility criterion to distinguish different parts of the adsorbed chain. The qualitative agreement with a theoretical model is also rather good.

More detailed experiments focusing on the relaxation time of the adsorbed segments are also possible, and a range of CPMG experiments on adsorbed terminally grafted poly(ethylene oxide) chains on polystyrene latex have been reported.²² As strongly dipolar-coupled spins are not visible in these experiments, the results reflect the mobility of segments that are part of the anchored chains but are not in direct contact with the particle surface. The mobility of the polymer segments is complex and anisotropic, though some qualitative description of the dynamics is possible, since the major contribution to the relaxation process is the segmental dynamics. The results show that as the surface-grafted amount increases, the average spin–spin relaxation time decreases, corresponding to increased intermolecular interaction. On increasing the chain length the average relaxation time increases, because the longer chains have more mobility, especially at the ends far from the interface. These changes reflect the change in overall mobility of the so-called ‘loops’ and ‘tails’ of the adsorbed polymer layer.

In more complex systems consisting of block copolymers of vinyl pyridine and styrene, both high-resolution ¹³C and ²H methods have been successfully employed to detect the binding and mobility of the adsorbed blocks.²³ This work showed that the vinyl pyridine groups of the copolymer were preferentially bound to the surface. The unadsorbed styrene segments were found to have a different mobility to the same segments when free in an equivalent concentrated solution. It was suggested that the strongly adsorbed vinyl pyridine segments restricted some of the motional modes of the adsorbed styrene.

Cross polarization between ²⁹Si atoms in the substrate and adsorbed poly(vinyl alcohol) has also been used to view surface and near-surface polymer segments selectively and to estimate the distance ratios of the hydroxyl groups and the polymer backbone to the silica surface.²⁴

The solvent relaxation method can also be applied to adsorbed polymers and the results show that the observed

Figure 7 Poly(ethylene oxide) (PEO) (molecular weight 20 kDa) desorption from silica by increasing the volume fraction of displacer $\phi(d)$: (○) adsorbed amount train segments for dimethylformamide as displacer; (●) total adsorbed amount for dimethylformamide as displacer; (Δ) adsorbed amount train segments for dimethyl sulfoxide as displacer

relaxation rate enhancement is due to adsorbed polymer segments in close proximity to the surface.^{25,26} One very useful application of this method is to find the critical displacement condition. This may be carried out by measuring the relaxation enhancement as a function of displacer concentration (in this case dimethylformamide). Figure 7 shows such a plot, clearly indicating the point when all the polymer has been desorbed and the relaxation rate reverts to that associated with the bare particles.

NMR relaxation methods have been applied extensively to investigate the structure and dynamics of polymer melts near particle surfaces. Several zones have now been identified where the bulk polymer mobility has been slowed by interacting either directly with the particle surface, or indirectly through entanglement with the surface-adsorbed chains.²⁷ The detailed analysis of the relaxation times originating from these different regions is complex, and thus far only a qualitative description has been given. A full description of these systems is beyond the scope of the present article.

6 POLYMER–SURFACTANT INTERACTIONS

NMR is an ideal technique for investigating polymer–surfactant interactions, and many reports appear in the literature which describe the use of these methods to good effect. We shall cite two recent examples of the detail that can be elicited from NMR measurements of these systems.

The interactions of surfactants with gelatine is of commercial importance to the photographic industry, and hence a detailed understanding of how the surfactant binds to the protein under different solution conditions (pH and ionic strength) is of continuing interest. High-resolution ¹³C chemical shift data show that for sodium dodecyl sulfate (SDS) only the two carbon atoms nearest the headgroup are affected by interactions with gelatine.²⁸ Table 1 shows these data and compares them with SDS–poly(vinyl pyrrolidone) interactions.

The low-frequency shifts seen for both polymers are likely to be caused by desolvation of the headgroup water by the

Table 1 ^{13}C Chemical Shifts of SDS Relative to *p*-Dioxane

Carbon No.	1% SDS/Hz	1% SDS + 5% gelatine/Hz	Δ (SDS-gelatine)/Hz	Δ (SDS-PVP)/Hz
1	5222	5182	-40	-94
3	1906	1923	+17	+60
10	2387	2392	+5	+54

polymer. The high-frequency shifts may be associated with the fact that more SDS micelles are present in the system as the gelatine (or, more specifically, its associated counterions) lowers the CMC of the SDS by nearly an order of magnitude. The spectrum of the gelatine itself is also quite revealing, showing that specific resonances (e.g. the aspartic and glutamic acid groups) are unaffected by SDS, but that the linewidths associated with the cationic residues and the hydrophobic groups become progressively broader with increasing SDS concentration.

In another ^{13}C study,²⁹ the interaction of SDS with poly(ethylene oxide) has been investigated as a function of surfactant concentration. When the polymer is saturated with SDS (above its CMC) the NMR relaxation results indicate a dramatic slowing down of the motion of the polymer segments attached to the micelles, even though these represent only a small fraction of the total number of segments. However, the whole system is dynamic, and fast exchange occurs between free monomer and free and adsorbed micelles.

7 PARTICLE/EMULSION CHARACTERIZATION

In any colloidal dispersion it is essential to know the surface area and dispersed state of the system. For particle systems we have seen that the relaxation rate enhancement provides a monitor of the aggregation state (available surface area), but other NMR methods can be used. For example, the flow of solvent through a suspension can be used to infer the volume fraction of particles in the colloidal dispersion. In particular, NMR diffusion experiments have shown that the average diffusion coefficient of the solvent depends on the

particle concentration and also on the structure of any adsorbed layer present.³⁰ Effectively the diffusion path is lengthened by the obstacle.

For emulsions, where it is difficult to measure the size and/or volume fraction, NMR diffusion offers many advantages over more conventional methods such as light scattering where the sample must be diluted. Recently, NMR diffusion has been extended to obtaining particle size distributions by choosing a specific distribution function to interpret the attenuation data.³¹ Figure 8 shows data obtained from an NMR analysis, assuming a log-normal distribution and results from optical microscopy. The two approaches are in reasonable agreement, but of course the NMR approach can be used in many systems which are inaccessible to microscopy or any other optical technique

1 INTRODUCTION

Whilst most people have some idea of what constitutes a metal or a polymer, ‘ceramic’ is a less certain term. Dictionaries define ceramics in terms of pottery and earthenware; however, a more scientific definition is ‘nonmetallic, inorganic materials that are made or used at high temperatures’. The range of ceramics is very broad and covers both very old and very new materials. This article will be mostly concerned with what might be termed advanced structural ceramics, since it is for these materials that NMR has been most useful in characterization and in providing structural information. (The ceramic superconductors are covered in *High Temperature Superconductors*, and will not be discussed here.) These engineering ceramics are typically based on oxides or low-density covalently bonded materials such as silicon nitride or carbide. They are often compositionally complex and, in addition, many ceramics contain atoms of similar X-ray scattering factors such as silicon and aluminum, oxygen and nitrogen, or carbon and nitrogen, so that X-ray scattering techniques are of limited value for obtaining structural information. NMR is a particularly valuable investigative tool for ceramics because it is element- and site-specific. The chemical shift, which is the most often used NMR parameter to obtain structural information in these systems, is most sensitive to the local environment around the atom under investigation, i.e. the nature, number, and position of nearest-neighbor atoms with some sensitivity to the next neighbor shell but very little sensitivity to the structure beyond the fourth coordination sphere. Hence, NMR can be used to characterize poorly crystallized or glassy (see *Amorphous Materials*) samples and to study the formation of the crystalline phase from the amorphous precursor. Many practical ceramics are solid solutions of different compounds and thus, at least in principle, compositionally disordered (i.e. a particular site can be occupied by, say, either a silicon or an aluminum atom); the distinct shifts observed for each ‘local’ configuration are very useful in determining this local order.

2 CERAMICS OF SiC AND Si₃N₄

The sensitivity of NMR to small structural changes in these systems is illustrated by the ²⁹Si, ¹³C, and ¹⁵N shifts of two important ceramic materials, Si₃N₄ (using ¹⁵N-enriched

Table 1 The ²⁹Si, ¹³C, and ¹⁵N Shifts of the Different Polytypes of SiC and Polymorphs of Si₃N₄¹⁰

samples for Si₃N₄) and SiC, given in Table 1. The different polymorphs of Si₃N₄ and polytypes of SiC all have readily distinguishable shifts (except the 6H and 15R polytypes, which differ only slightly in the stacking order). It can be seen that ¹⁵N is a particularly sensitive probe: each nitrogen is bonded to three silicon atoms, [NSi₃], yet the different sites have shifts which cover ~20 ppm in both Si₃N₄ polymorphs compared with only 2.1 ppm for the two silicon sites in α-Si₃N₄.^{1–6}

Because of the differences in spectra of the different polymorphs and polytypes, the phase purity of a particular material (often very important in determining the final product of a reaction) can be readily determined. Figure 1 shows, as an example, the ²⁹Si resonance of two samples of Si₃N₄ which differed only slightly in preparation conditions. Whilst both spectra show two lines indicative of the presence of α-Si₃N₄, in the upper spectrum the lines are of unequal intensity, and careful inspection shows that the right-hand line is slightly shifted from the value expected for pure α-Si₃N₄, indicating that some β-Si₃N₄ is present. The amount can be estimated by subtraction to an accuracy of order 1%, which is difficult to achieve using other techniques. However, one problem with NMR investigations of spin $I = \frac{1}{2}$ nuclei in ceramic materials is their very long spin–lattice relaxation times, T_1 , which can make experiments fairly time-consuming or difficult. Typically, in pure samples, T_1 of ²⁹Si, ¹³C, and ¹⁵N can all be >1000 s, and in fact in one experiment on SiC⁴ no signal was observed even after allowing the sample to polarize in the magnet field for 96 h! For samples with more than one site it is therefore important for quantitative results to make sure that possible differences in T_1 of the different sites have been investigated.

3 OXYNITRIDE CERAMICS

A number of oxynitride ceramics, particularly the ‘sialons’, have practical applications as high-temperature engineering components. The simplest (in the compositional sense) of these ‘sialons’ are those based upon the β-Si₃N₄ structure into which alumina has been substituted. These β’-sialons have the general formula Si_{3–x}Al_xO_xN_{4–x} (0 ≤ x ≤ 2). The ²⁹Si spectrum changes very little with alumina substitution even for x = 2, which seems to indicate that silicon is always surrounded by nitrogen.¹ If this is the case, then aluminum will have a range of tetrahedral AlO_yN_{1–y} (y = 0, . . . ,4)

Figure 1 The ^{29}Si spectrum of two samples of Si_3N_4 . The lower spectrum is pure $\alpha\text{-Si}_3\text{N}_4$, while the upper is from a sample with 79% $\alpha\text{-Si}_3\text{N}_4$ and 21% $\beta\text{-Si}_3\text{N}_4$

environments. In the case of mixed AlON tetrahedra, one can expect there to be a very large electric field gradient (EFG) at the aluminum site; furthermore, because of the different possibilities for the arrangement of the oxygen and nitrogen around the aluminum, there will be several different EFGs associated with each possibility. Thus, very broad ^{27}Al lines are to be expected. In fact in early experiments at 8.45 T it was found that because of the extreme breadth of the line only a small fraction of the ^{27}Al was being observed, the fraction increasing with oxygen content because more AlO_4 tetrahedra which have relatively smaller EFGs are formed.⁷ Later work at 11.7 T using a probe with a short ($\sim 2\ \mu\text{s}$) dead time and fast (16 kHz) spinning was able to observe more of the aluminum present. A broad line from AlO_4 tetrahedra at 68 ppm for $x = 2$ ($\text{SiAl}_2\text{O}_2\text{N}_2$) shifts to ~ 75 ppm, and further broadens as x decreases. The peak at ~ 75 ppm was assigned to AlO_3N .⁸ A small shoulder at 89 ppm, probably from AlO_2N_2 , is also visible for all samples. It should be noted that if the aluminum and silicon were randomly distributed, then AlO_4

Figure 2 Schematic representation of the local structure of β' -sialon with $x = 2$ (i.e. $\text{Si}_{3-x}\text{Al}_x\text{O}_x\text{N}_{4-x}$ or $\text{SiAl}_2\text{O}_2\text{N}_2$). The atoms in columns 1, 4, and 6 are above the plane of the paper, those in column 3 below, with columns 2 and 5 in the plane. The repeat unit along c is between the lines r . x are defects within the layers. (Adapted from Dupree et al.⁷)

would not be dominant even at $x = 2$, and mixed tetrahedra for ^{29}Si would be expected. When combined with the ^{29}Si data the ^{27}Al results strongly indicate a 'microdomain' type of structure in this material. A schematic diagram of this is shown in Figure 2. For small x the thickness of the AlO_4 'block' is reduced, leading to a rapidly increasing amount of mixed AlON tetrahedra.

Many practical oxynitride ceramics require sintering aids in their manufacture, and these react with the SiO_2 found on the surface of the Si_3N_4 grains, forming glassy intergranular phases. Study of these phases and their crystallization products is important in achieving an understanding of the limiting factors which determine the high-temperature properties of these ceramics. One popular aid in sintering is Y_2O_3 , and a number of compounds formed in the Y-Si-Al-O-N have been studied by NMR, as has the crystallization behavior of the glasses formed in this system. Initial measurements on ^{29}Si in this and related systems have determined the shifts of the various compounds, such as $\text{Y}_2\text{SiAlO}_5\text{N}$, YSiO_2N , etc., which are formed and helped to delineate the shift ranges of the $\text{SiO}_x\text{N}_{1-x}$ ($0 \leq x \leq 2$) tetrahedra shown in Figure 3.^{9,10} Note that, as with SiO_4 tetrahedra where there are different numbers of bridging oxygens, there is considerable overlap in the shift range of each local structural unit so that the number of oxygen and nitrogen neighbors cannot be unambiguously determined by the shift position alone. For a proper understanding of the local structure, full multinuclear studies are needed, and ^{15}N on enriched samples has been quite helpful in clarifying several issues. In general, it is found that when nitrogen is coordinated to three silicon atoms, $[\text{NSi}_3]$, the shifts are typically 40–80 ppm, whereas when coordinated to two silicon atoms, $[\text{NSi}_2]$, it resonates in the range 90–160 ppm.⁵ When a glass of the composition

Figure 3 Silicon-29 shift ranges in oxynitrides showing the effect of differing numbers of oxygen neighbors. (Adapted from Dupree et al.¹⁰)

$Y_{1.04}Si_{1.27}Al_{1.27}O_{4.8}N_{0.8}$ was crystallized at $1100^{\circ}C$ the ^{29}Si spectrum showed that six different compounds containing silicon were present including β' -sialon and Si_2N_2O , both of which are also evident in the ^{15}N spectrum. The ^{15}N spectrum also showed a broad peak at ~ 148 ppm and a sharp peak at 285 ppm. The former was shown to be from metastable Y_2SiAlO_5N , where nitrogen coordination would be either $[NSi_2]$ or $[NSiAl]$, by annealing at $1250^{\circ}C$ when both the ^{29}Si signal from this phase and the ^{15}N line at 148 ppm were markedly reduced. The peak at 285 ppm was identified as nitrogen substituted into yttrium aluminum garnet, $Y_3Al_5O_{12}$ (YAG), which is a major phase present. Analysis with TEM-EDAX showed that in the crystalline YAG approximately 14% of the aluminum was replaced by silicon, and it is likely that nitrogen will concurrently substitute for oxygen to maintain charge balance. The shift of this peak is much larger than for $[NSi_2]$ sites, so the most likely local environment is a nitrogen coordinated to a single silicon atom at the tetrahedral site in YAG and a vacancy at the octahedral aluminum site, i.e. $[NSi^*]$.

4 ZIRCONIA CERAMICS

Zirconia (ZrO_2) is an important high-toughness engineering ceramic which in its practical form is usually a mixture of several different crystallographic phases and/or is stabilized by some substituent such as yttrium or magnesium. Neither ^{91}Zr nor ^{17}O (unless enriched) can be regarded as ideal NMR probes, both have spin $I = \frac{5}{2}$, and whilst the natural abundance of ^{91}Zr at 11.2% is enough for NMR experiments (the sensitivity is 2.9 times ^{29}Si) the quadrupole moment is quite large such that in noncubic environments the linewidth is much too great for narrowing techniques such as MAS or DOR to be effective. Oxygen-17 has a much smaller (10^{-2}) quadrupole moment than ^{91}Zr , such that in an ionic environment such as ZrO_2 the EFG is quite small, the quadrupole coupling constant χ ($= e^2qQ/h$) being less than 3 MHz. In this case, despite the natural abundance of ^{17}O being only 0.037%, it is possible (with considerable averaging) to obtain spectra from unenriched materials that clearly distinguish between the tetragonal phase with one oxygen site ($\delta \approx 380$ ppm), the monoclinic phase with two sites ($\delta \approx 325$ and 401 ppm),

and the cubic phase with a broad line at ~ 375 ppm from the disorder due to vacancies in the structure.¹¹ Natural abundance ^{17}O experiments are time-consuming, however, and of limited practicality for day-to-day examination of these materials.

The phases of ZrO_2 zirconium have either seven (orthorhombic and monoclinic) or eight (cubic and tetragonal) oxygen neighbors, and thus the ^{91}Zr chemical shift difference between these phases is likely to be small. However, because of differences in local symmetry the ^{91}Zr EFG and the asymmetry parameter, η , are likely to be very different, and thus the phases can be distinguished by their quadrupolar lineshapes. The very large linewidth (~ 500 kHz in a 9.4 T field) means that the spectrum is best acquired on a static sample point by point. An advantage of a static NMR experiment is that the sample does not have to be powdered, which on this type of material may change the relative phase content via the phase transformation (tetragonal $\rightarrow$ monoclinic, tetragonal $\rightarrow$ orthorhombic). The spectra of cubic, monoclinic, and a fired, partially stabilized zirconia (PSZ), acquired at 25 kHz intervals using a spin echo sequence, are shown in Figure 4.¹² In the cubic phase (which contains ~ 13.5 mol% MgO for stabilization) the presence of

Figure 4 The ^{91}Zr spectra of several forms of ZrO_2 . (a) Magnesia-stabilized cubic zirconia (13.5 mol% MgO), (b) monoclinic ZrO_2 , and (c) tetragonal ZrO_2 (MS grade MgPSZ). The minor peaks are from residual monoclinic (m) and cubic (c) phases. (Adopted from Bastow et al.¹²)

oxygen vacancies, needed for charge balance, means that there will be a distribution of quadrupolar coupling constants; thus, a broad featureless line is observed and any structure is lost. The monoclinic phase is well fitted by a line with $\chi = 23.1$ MHz and $\eta = 0.1$, whilst the spectrum of MS grade PSZ is narrower ($\chi = 19.1$ MHz, $\eta = 0$), showing that it is mostly tetragonal with some monoclinic and cubic phase material present.

1 INTRODUCTION

NMR imaging of ceramics provides a wide range of opportunities for microscopic imaging of both liquids^{1–3} (*Image Formation Methods*) and solids^{4–6} (*Imaging Techniques for Solids and Quasi-Solids*). Techniques for imaging macroscopic samples of liquids are well developed and finding wide application in medical imaging. Techniques that are appropriate at the microscopic scale and for solid objects are only now being developed, however. Part of the reason these areas lag behind medical imaging is due to difficulties associated with the broad linewidth of solids, the low sensitivity of small samples (see also *NMR Microscopy: Resolution*), the large signal attenuation from molecular diffusion in a strong magnetic field gradient⁷ (see also *Diffusion and Perfusion in MRI*), and the susceptibility shifts from small heterogeneities within a sample⁸ (see also *Susceptibility and Diffusion Effects in NMR Microscopy*). The underlying cause, however, is the widespread realization that many of the most pressing imaging applications are in the medical arena. This difference is apparent in the way new techniques are being developed; most techniques for medical imaging are developed for specific applications, while many of the developments in solid state imaging and microscopy are focused on a challenging NMR problem. Structural ceramics, however, present a set of important real-world problems in processing that require imaging techniques, both to characterize the general processing conditions and for nondestructive evaluation (NDE) of critical components.^{9,11}

Although high performance structural ceramics possess superior mechanical and chemical properties, they are subject to catastrophic failure, and it is this failure mechanism that limits their applicability. These failures arise from defects in the sintered ceramic. A goal of ceramic imaging is to detect those defects that are larger than a critical size of approximately 100 μm . It is interesting to contrast ceramics to polymers, where imaging is primarily directed towards characterizing conditions of processing. Even though most imaging studies of solids are of organic polymers (see also *Polymer MRI*), there are extremely few applications where the costs of MRI NDE methods could be supported by a polymer product. In ceramics, however, a piece can be costly

to manufacture and it may be critical that it does not fail. Under these conditions, it is reasonable to consider using MRI as a method for NDE.

Ceramics are formed by complex thermal and chemical processing. First, ceramic powder is combined with an organic binder, which is mixed to form a solid green-state ceramic. These green-state ceramics can then be shaped prior to sintering. Often the sintered ceramic is nearly the finished product, and only a final finishing or machining step is required. The binder, or mixture of binder and plasticizer, has as its primary component a waxy organic polymer. These materials have T_2 values for ^1H of a few to 10 ms at room temperature and T_1 values of a few hundred milliseconds. The green-state ceramic can therefore be easily characterized by NMR techniques that, while not of high resolution, are certainly not in the solid state regime. After the sample is sintered, the ^1H content of the ceramic is minimal, and heteronuclear solid state techniques must be employed (see also *Ceramics*).

The successful manufacture of a structural ceramic requires that the inevitable flaw content be controlled. These flaws include cracks, voids, inclusions, and density variations. The idea of NDE in ceramic processing is to intercept defective pieces early in the manufacturing process, since each successive stage tends to be more costly. A green-state ceramic is relatively inexpensive and easily formed, but the energy costs of densification and sintering the material are quite significant. Finally, the labor costs associated with finishing a complex part can be very high. Ideally then there should be at least two NDE steps, one of the green-state material and a second of the sintered material. Since the NMR properties of the ceramic are very different in these two states, the imaging methods will also vary.¹²

An obvious question is why employ NMR to characterize the sintered material rather than X-ray computed tomography (CT) methods? The sintered sample is a complex mixture; in addition to the ceramic matrix there may be ceramic fibers, or whiskers added to the material to improve the strength and prevent catastrophic failure, and one needs to distinguish between sintered ceramic and agglomerates of additives, as well as detecting voids and variations in density. The material is therefore too complex for simple analysis by X-ray CT. Energy selected X-ray techniques are applicable, but these methods are not widely available. With NMR there is a great potential for chemical selectivity, particularly with regard to many of the quadrupolar nuclei that are used in ceramics, and it is the information content that drives the continuing development of NMR materials-imaging techniques.

Imaging techniques are not restricted to observing the ceramic matrix directly since the ceramics contain voids (both in the sintered and in the green state), and these voids may be filled with fluids which are observable via liquid state techniques.^{13–15} Additionally, the binder in the green state can be swelled by a solvent that then facilitates the imaging of the binder distribution, by reducing its linewidth, or can be observed itself. There are similarities between imaging liquids in ceramics and oil core imaging (see also *Oil Reservoir Rocks Examined by MRI* and *Well Logging*), but ceramics have the benefit of magnetic purity, while oil cores often suffer from large concentrations of magnetic material.

Instead of measuring an image to obtain the absolute concentration of a species throughout the sample, it is occasionally

desired to record statistical information regarding the entire sample, such as the porosity, the pore size distribution, or the tortuosity.¹⁶ These quantities and others can be measured via a variety of diffusive scattering techniques (see also *Diffusion in Porous Media*). Since these measurements are average properties of the entire sample, the sensitivity is good, and spatial information may be obtained at much finer resolution than is possible with imaging methods.

One difficulty that has yet to be adequately addressed in ceramic imaging (or in materials imaging in general) is that of sample size. For solid state methods, it is usually the case that the rf field needs to be sufficiently large to dominate the variation of the local field across the sample. Therefore the samples tend to be small, and almost all solid state imaging has been performed on samples of less than 1 cm in diameter. A similar problem is encountered in microscopy where the sample is constrained to be sufficiently small that effective magnetic coupling of the spin response and the receiver is maintained. However, the critical size of defects does not scale with the sample size, and so, regardless of the size of the piece, image resolution needs to be at the sub-100 μm scale.

Not all ceramics are synthetic; bone and teeth have many properties in common with the synthetic structural ceramics discussed here, and these have also been studied.^{17,18}

2 AN OVERVIEW OF IMAGING METHODS

Much of the power of NMR spectroscopy and imaging arises from the flexibility to tailor an experiment to the sample and the information desired. Therefore, there is a broad spectrum of methods that may be chosen to optimize the resolution, sensitivity, and contrast of an image (see also *Image Formation Methods*). Here the various methods used in imaging ceramics will be introduced. Ceramic samples range from liquids in porous materials through waxy solids to rigid solids, and the techniques used in imaging are similarly diverse.

Nearly all imaging experiments involve a precession period in the presence of a magnetic field gradient. Since the normally dominant Zeeman interaction is directly proportional to the magnetic field strength, this precession labels the spins according to their location within the gradient field. It is useful to distinguish between encoding by phase and by frequency. Data are not acquired until the end of the phase encoding period, and so it is only the overall phase angle of spin precession that is observable. In frequency encoding, data are acquired continuously, and the periodicity of data acquisition allows the frequency of spin precession to be determined. The criteria for resolution and sensitivity are different for these two approaches. For frequency encoding, the resulting image is a convolution of the spin density and the NMR spectrum, so the NMR linewidth acts as the system point-spread function and limits the obtainable resolution, the resolution being given by the linewidth divided by the gradient strength. If the gradient is increased to obtain a higher resolution, the frequency spread of the resolution element is broadened and the experimental sensitivity is correspondingly reduced. In phase encoding (which we will limit here to constant-time methods),¹⁹ the NMR linewidth is decoupled from the image representation, and a true spin density can be measured. This result is a consequence of being at high field where the internal spin

Hamiltonians and the gradient Hamiltonian commute. The overall spin evolution is then simply the sum of the evolution due to the internal interactions and that due to the gradient. In a constant-time experiment the internal Hamiltonians are constant and the spin evolution due to them is reproducible. The linewidth still limits the sensitivity, however, since the NMR signal decays over the time period of the spatial encoding.

One approach to obtaining higher resolution is to increase the gradient strength and accept the loss in sensitivity. An appealing alternative is to use line-narrowing methods that can recover both sensitivity and resolution²⁰ (see also *Line Narrowing Methods in Solids Imaging of Wide-Band Systems by Line-Narrowing Methods*). A good line-narrowing method may reduce the linewidth by a factor on the order of 1000, while preserving the full sensitivity. For an imaging experiment, the resolution is increased as the reduction in the linewidth, and the sensitivity also increases due to the reduction in the bandwidth.

There are two general classes of coherent averaging techniques for reducing the NMR linewidth: those that manipulate the spin state of the system through a series of rf pulses (see also *Average Hamiltonian Theory*); and those that manipulate the spatial orientation of the spin system so as to average anisotropic contributions to the linewidth (see also *Magic Angle Spinning*). The two approaches may also be applied simultaneously (see also *CRAMPS*). All three methods have been applied to solid state imaging.⁵ These coherent averaging techniques are, however, often complex to apply, and the result is somewhat sample dependent. Coherent averaging of internal interactions reduces the linewidth by modulating effective spin interactions such that the time average is either reduced or zero. The success of these methods depends on the accuracy of the modulation scheme and on the absence of competing modulations (particularly those from random molecular motions). Coherent averaging is very useful where there is little molecular motion (such as for engineering plastics, where these methods have been widely applied), or where there is high-frequency motion of limited angular displacements (such as in elastomers). One can expect that imaging of sintered ceramics will greatly benefit from line narrowing,^{21,22} but the case is not so clear for the waxy binder of green-state ceramics.

There are a variety of contributions to the solid state linewidth (see also *Internal Spin Interactions and Rotations in Solids*). Most coherent averaging methods have aimed at removing homonuclear dipolar coupling (particularly for ^1H imaging), chemical shift anisotropies, inhomogeneous interactions, and all of the above via time-suspension cycles. Heteronuclear line narrowing experiments have also been performed with broadband ^1H decoupling. In the special case of half-integer quadrupolar nuclei, which have $m = -\frac{1}{2}$ to $m = +\frac{1}{2}$ transitions, the same methods that sharpen homonuclear dipolar couplings will remove the second-order quadrupolar broadening.²² The first-order quadrupolar terms do not broaden this transition (see also *Quadrupolar Nuclei in Solids*).

Nearly every ceramic imaging study requires some specialized instrumentation, either in the form of strong gradients, or as a setup for coherent averaging methods. Magnetic field gradients of a few tesla per meter are difficult to achieve over large volumes, typically have long switching times and large induced

eddy currents, as well as being difficult to contain mechanically, and to cool. For these reasons back-projection methods are often used to avoid the necessity of gradient switching (see also *Projection-Reconstruction in MRI*). The stray field imaging experiment²³ is a variation of the large gradient back-projection method where each one-dimensional projection of the spin density is mapped out successively while translating the sample through the strong gradient which exists in the fringe field of a high field magnet. The resolution is dependent on the excitation bandwidth of the experiment and can be quite high, although the sensitivity of the experiment is generally low. This is an incoherent, constant-time imaging technique. Line-narrowing techniques typically require only very modest gradient strengths, but often need better than average rf control and setup, and for optimal results extremely short (5 μ s) gradient pulses.²⁴ Since the spin state of the system is being modulated, the gradient Hamiltonian no longer commutes with the effective internal Hamiltonians. Therefore, the gradient must be carefully applied to avoid the gradient interfering with the line narrowing.

3 IMAGING OF GREEN-STATE CERAMICS

NMR imaging techniques are being actively developed in the area of nondestructive evaluation of green-state ceramics.^{25–28} The goal of the method would be to acquire a correct spin density image of the binder distribution throughout a modest sized sample to help detect any nonuniformity in the binder distribution and to locate cracks, voids, and other defects.

For the purposes of ^1H NMR, green-state ceramics are waxy solids, and far from ideal samples. They have too little motion to exhibit sharp resonances, and yet sufficient motions that coherent averaging schemes tend to fail. Examples of binder material include low-molecular-weight poly(ethylene oxide), poly(vinyl alcohol), and poly(ethylene terephthalate). Although waxy materials are often compared to elastomeric materials, there is a large difference in the NMR properties. Elastomers tend to have restricted molecular motions, which are fast on the NMR timescale. Modulation rates in coherent averaging methods tend to be in the region of kilohertz to a few tens of kilohertz. Molecular motions in elastomers are significantly faster than this. Waxy materials tend to have less well-defined motions that have a broad frequency spectrum with significant contributions in the appropriate range for coherent averaging. The residual linewidth in an elastomer arises from an incomplete averaging of internal Hamiltonians based on fast but restricted motions. The linewidth in waxy materials arises from an incomplete averaging based on both restricted motions and slower motions. Elastomers are therefore easily line narrowed since in the NMR experiment the residual Hamiltonians from the fast motions are static and of modest size. Waxes are more difficult to line narrow since the residual interactions are time dependent.

There are three apparent options to recording high-resolution images of green-state ceramics:

1. Use large magnetic field gradients with the sample at room temperature to achieve the desired resolution at a sacrifice of sensitivity.
2. Heat the sample until the line sharpens and use liquid state techniques.

3. Cool the sample to freeze out molecular motions and then use solid state techniques.

The use of large gradients has the advantage of least impact on the sample, as well as of avoiding artifacts. Heating the sample must be performed with care to stay below the temperature where sample integrity is lost. Reducing the linewidth increases the sensitivity, but note that the entire binder may not narrow. Perhaps only a fraction (such as a plasticizer, or the low-molecular-weight cut) will narrow, and then the image will not yield a true representation of the spin density. Cooling the sample and employing solid state techniques has the advantage of preserving the true spin density; however, the spin-lattice relaxation time is also dependent on molecular motions and may lengthen appreciably. Also care must be taken to ensure that the binder does not phase separate or crystallize.

To date the preferred methods have been to employ modestly strong gradients, but the resolutions required for NDE applications have not been achieved. The progress in this area has been recently reviewed.⁹ Some examples are two-dimensional (2D) images of a 2.54 cm diameter green-state ceramic with both Fourier imaging and constant-time techniques.²⁵ The sample contained 15.5% by weight of binder, and using a gradient of 0.033 T m^{-1} with an encoding time of 1.98 ms; a resolution of $552 \mu\text{m}$ was achieved in the Fourier imaging experiment and of $326 \mu\text{m}$ in the constant-time experiment. The Fourier image was acquired in 25 min and, as expected, the constant-time experiment took much longer, requiring 220 min. Back-projection techniques were employed¹¹ to acquire images of a 2.5% by weight green-state ceramic with 0.35 T m^{-1} gradients at a resolution of $175 \mu\text{m}$.³ However, the data required a collection time of 18 h. These experiments do as much to point out the remaining difficulties as they do to show the promise of the method. Clearly, much work is still required to increase both the resolution and the sensitivity of the methods.

4 IMAGING OF SINTERED CERAMICS

Probably the most underexplored area of ceramic imaging is of the final sintered piece. Since the proton content of the sintered ceramic is extremely low, many of the methods for solid state imaging that have been developed for proton-rich solid polymers are not directly applicable. To characterize the sample by direct observation of the solid ceramic matrix, the available nuclei are predominantly Al, Si, B, N, and P. It is expected that the sensitivity will be lower than seen in ^1H images of bulk solid polymers due to a combination of low spin concentration, low magnetogyric ratios, and quadrupolar interactions. For now, both Si and N can be excluded on sensitivity grounds: ^{29}Si has low abundance and has unacceptably long T_1 values in the solid state, and ^{15}N has low abundance and a low magnetogyric ratio. While ^{14}N is reasonably abundant, it has spin = 1 with an appreciable quadrupole coupling constant and a large chemical shift anisotropy.

The other three nuclei, ^{27}Al , ^{11}B , and ^{31}P , are all reasonable candidates for solid state imaging experiments, and some preliminary results have been reported for each.^{29,30}

Phosphorus-31 is 100% abundant with spin = $\frac{1}{2}$, so where it is present in the ceramic the imaging approach is reasonably

straightforward. The linewidth is dominated by homonuclear dipole–dipole couplings and chemical shift anisotropy, so here techniques very similar to those used for multiple-pulse proton imaging will apply. Phosphorus-31 images have been recorded of biologically significant solid calcium phosphates where there was an appreciable proton content.²⁹ The ^{31}P linewidth was dominated by ^1H dipolar interactions, a facet which was used to increase the sensitivity via cross polarization and then decoupled during acquisition to reduce the linewidth. An important feature of the cross polarization experiment is that the recycle time is dependent on the T_1 of ^1H and not on the longer T_1 of ^{31}P .

Aluminum-27 and ^{11}B are both half-integer quadrupolar nuclei and hence both have an $m = -\frac{1}{2}$ to $m = +\frac{1}{2}$ transition which can be conveniently observed. These are attractive nuclei for imaging since the central transition is not broad compared to the spectral width of broadcast and receive channels of solid state spectrometers, and can be further sharpened by multiple pulse methods.²² Another virtue of the quadrupole interaction is that it leads to short T_1 values, so the experiment can be efficient in terms of data acquisition. Strong gradient methods have been used to record images of phantoms using both of these nuclei,³⁰ including a 2D ^{11}B image of a borosilicate glass sample (6 mm field of view) at a resolution of $520\ \mu\text{m}$ using a gradient of $1.55\ \text{T m}^{-1}$ and an experimental time of 133 min. For a similar phantom composed of γ -alumina, an image of ^{27}Al was obtained at the same resolution in 90 min with a gradient of $2.25\ \text{T m}^{-1}$.

The apparent nutation frequency of the central transition of half-integer quadrupole nuclei is dependent on the strength of the quadrupole coupling constant (see also *Nutation Spectroscopy of Quadrupolar Nuclei*), and hence the nutation frequency can be used to introduce contrast into an image. In this way pure images of the alumina and aluminate fractions were obtained from a composite phantom.³⁰

5 IMAGING OF FLUIDS IN CERAMICS

Fluids can be introduced into either sintered ceramics or green ceramics. In the case of sintered materials the fluid may be vacuum impregnated and the fluid imaged to look for defects. In the case of green ceramics, the fluid can either swell the binder, or be introduced into the pore structure of the material. It has been suggested that the fluid can be removed for NDE, although this addition of extra processing steps is undesirable. The spin density image allows one to characterize the porosity of the material and to easily find defects into which the fluid can flow. A perhaps surprising result is that the image of the fluid can provide information about defects that are inaccessible to the fluid, based on local variations in the bulk magnetic susceptibility (see also *Susceptibility and Diffusion Effects in NMR Microscopy*). The variation in the bulk magnetic susceptibility throughout a heterogeneous sample implies that, when placed in a magnetic field, the magnetic field inside the sample will be spatially varying. The result is a complex local distortion of the magnetic field in the vicinity of boundaries. If a defect in a ceramic material has a susceptibility that is significantly different than that of the bulk of the sample, the presence of the defect will appear as a resonance shift for spins that are adjacent but not in direct contact with the defect. In this fashion voids that are not filled

with fluid can still be detected via liquid state imaging. In favorable cases even agglomerates of fibers or other fillers may be detected.

Areas of susceptibility variations introduce distinct image distortions that are readily identifiable. It is also quite straightforward to test for their presence either by reorienting the sample in the field and repeating the experiment, or by employing an imaging experiment that is insensitive to susceptibility artifacts, such as constant-time imaging and refocused gradient imaging experiments.

Liquid state imaging methods have been used to follow the drying of slipcasting, and the uniformity of the resulting compact.³¹ Benzene that was vacuum impregnated into a green ceramic has been imaged in a matter of a few minutes at a resolution of $380\ \mu\text{m} \times 350\ \mu\text{m}$ for a 2 mm thick slice.¹² From these images the overall porosity could be observed along with some rather large defects that were intentionally introduced into the sample. These are relatively early results that have not been revisited and the low resolution was a result of the small gradient strengths employed at that time.

6 LOCAL MEASUREMENTS

Imaging allows the absolute spatial properties of a selected spin system to be recorded at a resolution of up to approximately $10\ \mu\text{m}$ by spreading the resonance line with a sufficiently strong gradient such that each volume element is resolved from its neighbors. Much below about $10\ \mu\text{m}$, diffusional losses and the limited number of spins in a selected cubic volume element greatly reduce the signal intensity. Therefore, absolute spatial information is not, presently, available at this and higher resolutions. Average local geometries may be characterized, however, by observing the temporal evolution of spin transport of all spatially distributed mobile spins simultaneously, thus avoiding the signal-to-noise limit on resolution. The resolution limits of these studies are only dependent on the gradient strength, the diffusion coefficient and relaxation times. For many samples the lower limit to resolution may be extended a factor of 100 below that of imaging methods. Some examples of the types of information that are available from these spin transport studies include: (1) self-diffusion constants, (2) compartment sizes and distributions, (3) eccentricities and volumes of compartments, (4) fluxes through semipermeable membranes, and (5) the existence and nature of wall relaxation. These quantities may be of interest in characterizing the packing of ceramic powders¹⁶ (see also *Diffusion in Porous Media*).

7 CONCLUSIONS

While much work still remains to be done, high performance structural ceramics is an area that can clearly benefit from techniques of high resolution NMR imaging. The problems that remain are to devise methods that increase the sensitivity and resolution for waxy solids, and to devise methods of studying relatively large solid samples while preserving high resolution.

1 INTRODUCTION

Soils are heterogeneous mixtures of organic substances, minerals and organomineral complexes. The organic substances include macromolecules lacking well-defined structures or repeating units. The minerals include poorly ordered or amorphous matter. These difficulties have hindered scientific studies of soil, leaving fundamental questions of structural chemistry open to debate until recent years. NMR spectroscopic studies have provided some convincing answers that broaden our understanding of the origins of soil characteristics, the influences of land management on soil fertility, and the fate of agrochemicals.

Soil organic substances were extracted, methylated, and dissolved in deuterated solvents for the earliest ^1H and ^{13}C NMR studies of soil chemistry.¹⁻³ These studies provided little worthwhile information. Much more detail emerged from a 1976 paper describing ^{13}C NMR spectra of soil organic substances in alkaline aqueous solution.⁴ The first ^{13}C CP MAS NMR spectrum of whole soil was published in 1981.⁵ The publication rate has now risen to an average of about one paper per month describing ^{13}C CP MAS NMR studies of humic substances. Solution ^{13}C NMR spectroscopy is used on occasions, and several other nuclei provide useful spectra.

This article is not intended as a comprehensive review. More complete references to relatively early work can be found in two books published in 1987.^{6,7}

2 SAMPLE PREPARATION

Soil organic substances are commonly separated into three fractions defined in terms of solubility. 'Humic acids' are not soluble in water under acid conditions, but are soluble under alkaline conditions. 'Fulvic acids' are soluble under all pH conditions. 'Humins' are not soluble under any pH conditions.

Humic acids generally account for the major part of soil organic matter. They have been characterized by CP MAS NMR or dissolved in aqueous alkali for solution NMR, the two procedures yielding similar patterns of signal intensities.^{8,9} Fulvic acids are hygroscopic and yield poor CP MAS NMR spectra unless they are carefully dried.¹⁰

Differences between ^{13}C CP MAS NMR spectra of humic acids and the corresponding humins are not as pronounced as might be expected for separation based on differences in chemical properties.^{11,12} It appears that differences in solubility are rather caused by differences in physical accessibility of the organic matter.¹¹ The NMR spectra of fulvic acids are usually distinctly different from the corresponding humic acids or humins,^{11,12} so humic acids are not representative of the organic matter in the complete soil.

Soil extracts can be used for NMR studies without fractionation into humic and fulvic acids. This procedure is particularly advisable in preparing samples for ^{31}P NMR,¹³ since phosphate esters could be hydrolyzed under the acidic conditions required for precipitation of the humic acid fraction. Sequential extraction procedures have been developed to remove over 80% of organic phosphorus from soils for solution NMR characterization.¹⁴

Removal of paramagnetic species such as Fe^{3+} can improve ^{13}C CP MAS NMR spectra of solid soils and humins.¹⁵⁻¹⁷ As a general rule, the ratio $\text{C}:\text{Fe}; > > 1$ is required for a good spectrum.¹⁵ Pretreatment by a mixture of HCl and HF has the added advantage of removing inorganic substances and therefore concentrating the organic matter.¹⁷

3 SIGNAL ASSIGNMENTS FOR ^{13}C

A typical CP MAS NMR spectrum of whole soil (Figure 1) shows overlapping signals that are grouped in four chemical shift ranges for discussion here.

Signals in the range $\delta = 10-50$ are assigned to alkyl carbon, including side chains in amino acids, structures derived from higher-plant polymers such as cutins and suberins, and structures formed by cross-linking between polyunsaturated

Figure 1 Carbon-13 CP MAS NMR spectrum (50.3 MHz) of Taupo Soil, A horizon: 7 mm diameter cylindrical rotor spun at 5.0 kHz, 1 ms contact time, 15 ms data acquisition time, 300 ms pulse delay, 10.6 h of data accumulation

microbial lipids.¹⁸ Input from microbial activity has been demonstrated by incubating soil with ^{13}C -labeled glucose.¹⁹ A signal near $\delta = 31$ is sometimes relatively strong in spectra of soil fractions sieved to select particles with dimensions less than $2\ \mu\text{m}$.^{20–22} This signal has been assigned to polymethylene chains, including organo-clay complexes.²⁰

Signals in the range $\delta = 50$ – 110 are assigned primarily to *O*-alkyl carbon, i.e. oxygen-substituted carbon in alcohols and ethers, including plant carbohydrates and their degradation products. These substances are relatively abundant in fractions sieved to select coarse particle sizes,²² and are particularly well preserved in cold climates.²³ This chemical shift range includes signals between $\delta = 50$ and 60 assigned to *N*-substituted carbon in amino acids.⁴

Signals in the range $\delta = 110$ – 160 are assigned primarily to aromatic carbon. The question of whether aromatic substances form a major or minor component of soil organic matter has been debated as recently as 1985.^{24,25} Perhaps the best answer is that considerable variation has been observed. A band centered on $\delta = 130$ is particularly prominent in NMR spectra of organic matter found in soils that have been affected by fire.^{26,27} Signals in the range $\delta = 150$ – 160 have been assigned to oxygen-substituted aromatic carbon. The degree of oxygen substitution shows a strong negative correlation with soil development, perhaps as a result of selective degradation of the more highly substituted structures.²⁸

Signals in the range $\delta = 160$ – 210 are assigned to carbonyl carbon.²⁹ This region is usually dominated by a peak in the region $\delta = 170$ – 180 , assigned primarily to carboxylic acids. Secondary amides can also contribute to the peak.³⁰ The signal strength is usually stronger than would be expected from chemical analyses for carboxylic functional groups, and nitrogen contents fail to account for the discrepancies. Schnitzer and Preston concluded that 'it is possible that chemical methods do not react stoichiometrically with materials of high molecular weight, such as humic substances, because of steric factors.'²⁹

4 SIGNAL ASSIGNMENTS FOR OTHER NUCLEI

Poor signal dispersion has discouraged widespread use of ^1H NMR in soil science. Bands of partly resolved signals have been observed in the ranges $\delta = 0.8$ – 2.5 (alkyl), 3.3 – 3.8 (*O*-alkyl), and 6 – 8 (aromatic).³¹ Features within these bands have been assigned to more specific chemical structures.³² Aromatic protons can exchange with deuterons in solvent, resulting in underestimation of aromaticity.³³

After ^{13}C , ^{31}P is the nucleus most commonly used in NMR studies of soil. Some generalized signal assignments are shown in Figure 2. The sample was chosen for the diversity of chemical species. The orthophosphate monoesters include choline phosphate ($\delta = 3.5$) and inositol hexaphosphate (four signals).¹³ Orthophosphate diesters include phospholipids. Phosphonates are clearly distinguished by the chemical shift range characteristic of a direct carbon–phosphorus bond. This category includes phosphonolipids ($\delta = 20$) and their degradation products ($\delta = 18$).¹³ Many ^{31}P NMR spectra of pasture soil extracts show only a dominant signal near $\delta = 5$, assigned to inorganic orthophosphate, with a weaker band across the range $\delta = 3$ – 5 , assigned to orthophosphate

monoesters.³⁴ Some spectra of soil extracts include a signal near $\delta = -21$, assigned to polyphosphate chain units.¹³

The natural abundance of ^{15}N is so low that isotopic enrichment is necessary. Soil organic matter matures over periods of centuries, so only the first steps of humification can be studied by monitoring the fate of ^{15}N -enriched additives. At least three different chemical shift scales have been used in studies relevant to agriculture. The chemical shifts mentioned here are expressed in parts per million to high frequency from ammonia. Typical values are $\delta = 30$ – 70 for amine nitrogen, 90 – 120 for amide nitrogen, and $\delta > 120$ for heterocyclic nitrogen.³⁵ Chemical shifts have been reported for a number of specific substances considered relevant to the chemistry of humic substances.³⁵ When a soil humic acid was incubated with ^{15}N -enriched NaNO_3 , the ^{15}N CP MAS NMR spectrum of the product was dominated by a broad band at $\delta = 119$, assigned to secondary amides, e.g. in proteins.³⁶ The ^{15}N CP MAS NMR spectra of composts prepared with ^{15}N -enriched plant material are dominated by a peak assigned to proteins, with weaker signals at 83 and 71 ppm assigned to nucleic acids.³⁷

NMR is not normally the technique of choice for studies of inorganic matter in soil, but there have been exceptions.

Most soil silicates contribute ^{29}Si NMR signals in a broad band across the region $\delta = -80$ to -115 .³⁸ Fractionation of a soil into particle size ranges has been used to demonstrate the predominance of quartz ($\delta = -113$) in a coarse fraction, and layered aluminosilicates ($\delta = -92$) in a fine fraction.³⁹ One of the hydrated aluminosilicates, imogolite, contributes a relatively narrow peak at a distinctive chemical shift of $\delta = -78$.³⁸ Therefore, ^{29}Si NMR can be used to estimate the imogolite content of soil.

Solution NMR methods have been used to characterize aqueous ^{27}Al in plugs of soil.⁴⁰ Most of the signal strength was

Figure 2 Phosphorus-31 NMR spectrum (32.2 MHz) of an aqueous NaOH extract from Carrick tussock-grassland soil. Sample mixed with D_2O in a 10 mm tube; $12\ \mu\text{s}$ pulse width, $0.8\ \text{s}$ data acquisition time with proton decoupling, $5.0\ \text{s}$ pulse delay without proton decoupling, $79\ \text{h}$ of data accumulation. The soil properties are described elsewhere⁴³

found in a band from $\delta = -9$ to 12. This band was assigned to species with octahedral coordination, including complexes with humic substances. A relatively sharp peak at $\delta = 63.5$ was assigned to a polynuclear cation, believed to be more toxic to plants than the mononuclear cation.⁴⁰

5 RELIABILITY OF NMR RESULTS

Patterns of relative signal areas have been compared for ^{13}C NMR spectra of extracted humic substances run as solids and as solutions.^{8,9,41} The overall similarities have been encouraging, but sources of errors have been identified in both techniques.

In the case of solution NMR spectroscopy, it is necessary to choose a pulse delay that is adequate for both T_1 relaxation and suppression of NOEs. Preston and Blackwell drew attention to the need to consider magnetic field strength in selecting a suitable pulse spacing.⁸ Values of $T_1 < 0.2$ s have been reported for protonated carbon in solutions of humic substances run at a field strength of 1.87 T,⁴² but values in the range 0.2–0.8 s have been reported for experiments at 5.6 T.⁸ These observations are consistent with molecular motion including components with correlation times longer than required for the T_1 minimum. Values of NOEs are particularly low and values of T_1 are particularly long for carboxyl carbon, so the content of this chemical functional group can be underestimated unless the decoupler output is gated off during the pulse delay.^{8,42} A dramatic improvement in the strength of these signals has been reported for pulse delays increased from 0.5 to 5.0 s.⁴¹ A pulse delay of 2 s has been suggested for solution ^{13}C NMR at 63 MHz.⁸ Pulse delays as long as 20 s have been found necessary in ^{31}P NMR of soil extracts.⁴³

The choice of magnetic field strength should be considered in ^{13}C CP MAS NMR also. Fründ and Lüdemann reported $T_1(\text{H})$ values in the range 3–6 ms for humic matter run at 2.35 T, rising to the range 10–20 ms for the same sample run at 7.05 T.⁴¹ These values are fortunately all so short that the pulse spacing is more likely to be determined by the duty cycle of the spectrometer. It is important that the contact time should be long enough for adequate cross polarization, yet short enough to avoid the effects of variations in $T_{1\rho}(\text{H})$ between chemical functional groups. These two criteria conflict for most humic substances. On one hand, contact times as long as 1 ms are needed to achieve maximum signal strength for nonprotonated carbon, e.g. carboxylic carbon.⁸ On the other hand, values of $T_{1\rho}(\text{H})$ can vary between chemical functional groups, because of the heterogeneous nature of soil organic matter. This was particularly evident in a clay fraction, where values of $T_{1\rho}(\text{H})$ ranged from 2.0 ms for *O*-alkyl carbon to 6.2 ms for *O*-substituted aromatic carbon.⁴⁴ Variations in $T_{1\rho}(\text{H})$ can arise, e.g. from selective binding of metal ions to specific chemical structures.⁴⁵ A contact time of 1 ms seems to provide a reasonable compromise.⁴⁵

Paramagnetic ions such as Fe^{3+} can shorten values of $T_{1\rho}(\text{H})$ until organic matter in the immediate vicinity of each ion no longer responds to CP MAS NMR.⁴⁶ Interference from organic free radicals is not as important, as shown by a 'spin counting' experiment in which 97% of carbon in a solid ash-free fulvic acid responded to CP MAS NMR, despite the presence of organic free radicals.⁴⁶

6 APPLICATIONS

Soils are often classified according to their color, so studies of the origin of color can provide a fundamental basis for classification schemes. NMR experiments have shown that the more intensely colored humic and fulvic acids contain relatively high proportions of aromatic carbon.^{26,47} Humic substances in general display strong absorbance in the UV, tailing off across the visible region. Absorptivity at 272 nm has been found to be highly correlated ($r = 0.94$) with the strength of ^{13}C NMR signals assigned to aromatic carbon in humic acids.⁴⁸ Weaker correlations have been reported for fulvic acids.⁴⁹

CP MAS NMR has been used to demonstrate a correlation ($r = 0.997$) between the aromatic carbon content of humic acids and the partition coefficient for binding of pyrene.⁵⁰ This suggests that the chemical structure of humic material should be considered in any attempts to model the transport or fate of organic pollutants. Carbon-13 NMR has been used to demonstrate formation of covalent bonds between ^{13}C -labeled 2,4-dichlorophenol and humic acid.⁵¹ Decreased herbicide activity in tilled soil has been attributed to the organic matter being in a more reactive state than in soil that was not tilled.⁵² The ^{13}C NMR spectrum of humic acid from the tilled soil showed a relatively strong band assigned to aromatic carbon, but the authors advised caution in the interpretation of the results, in view of the small magnitude of the observed differences and the small number of samples tested.⁵²

A combination of ^1H , ^{13}C , and ^{31}P NMR has been used to monitor degradation of a herbicide, glyphosate (*N*-phosphonomethylglycine), in soil.⁵³

Fecal fibre is rich in carbohydrates, particularly crystalline cellulose, contributing relatively sharp ^{13}C NMR signals across the region assigned to *O*-alkyl carbon.⁵⁴ These signals become weaker when feces are composted. In the case of composts formed from cattle manure, the relative signal area of the *O*-alkyl band dropped from 59% to 33% over a period of 147 days of composting.⁵⁵ CP MAS NMR has been described as the 'most quantitative procedure' of those tested for use in characterizing compost maturity.⁵⁶

Intensive land management practices are known to cause long-term decreases in soil organic matter. Carbon-13 NMR has been used in attempts at characterizing the residual organic matter. Divergent results indicate a complex dependence on the nature of the initial material and details of the management regime. Oades et al. found relatively high aromaticity in a red-brown earth cultivated for 60 years, compared with undisturbed soil.⁵⁷ On the other hand, Schulten et al. found relatively low aromaticity in soils cultivated for periods up to 35 years.⁵⁸ Schulten et al. found lowest concentrations of residual organic matter in soils treated with high doses of mineral fertilizers. It is possible that their results reflect the influence of fertilizers rather than the influence of crops. Preston et al. observed a decrease in the area of the *O*-alkyl band and a corresponding increase in the area of the alkyl band in CP MAS NMR spectra of peat cultivated for periods up to 15 years.⁵⁹ These changes may reflect the influence of plowing, exposing organic matter to biological oxidation. Skjemstad et al. studied soils cultivated for periods up to 45 years.⁶⁰ They found no detectable changes in relative signal areas across CP MAS NMR spectra, but the signals became broadened in the spectra of soils with the lowest concentrations of residual

organic matter. They suggested that a major mechanism for the relative stability of persistent soil organic matter may be a physical association with the inorganic component. The effects of cultivation are also evident in ^{31}P NMR spectra of soil extracts, the diversity of chemical species being greater in uncultivated soils than in corresponding samples of cultivated soils.⁶¹

Several authors have studied the influence of climate and vegetation on soil properties. A negative correlation ($r = -0.998$) has been found between rainfall and the strength of ^{13}C signals assigned to aromatic carbon in humic acids.⁶² The ^{31}P NMR spectra of soil extracts show a particularly wide diversity of chemical species for sites with high annual precipitation.⁴³ No correlations were found in a study of vegetation and its influence on the chemical structure of soil.⁶³

7 SEPARATING OVERLAPPING SIGNALS

The applications sketched above have been hindered by problems with overlapping signals, particularly in solid state ^{13}C NMR. Most authors describe soil organic matter in very general terms, e.g. distinguishing 'aromatic' or 'aliphatic' carbon. Some spectra show hints of variations in details within one or more of the bands. Several strategies have been suggested for separating these overlapping signals.

Dipolar dephasing suppresses CP MAS NMR signals from most CH and CH_2 groups, leaving signals assigned to nonprotonated carbon or protonated carbon in functional groups with some freedom for internal motion. This technique has been used to demonstrate differences between the degrees of aromatic substitution in different humic acids.⁶⁴

Proton spin relaxation editing exploits the heterogeneous nature of soil.⁶⁵ A proton inversion–recovery pulse sequence is combined with ^{13}C CP MAS NMR. Linear combinations of partly relaxed and fully relaxed spectra are generated to separate subspectra assigned to distinctly different forms of organic matter with distinctly different values of $T_1(\text{H})$. This procedure has been used to separate subspectra from the CP MAS NMR spectrum of a humic acid, suggesting that material extracted from clays may differ from material extracted from other soil fractions.²⁸ Variations in $T_{1\rho}(\text{H})$, mentioned above, could also be used for separation of subspectra.

2D NMR techniques show some promise for separation of overlapping signals. A ^1H – ^{13}C heteronuclear chemical shift correlation experiment has been used to construct a 2D NMR plot for a sample of fulvic acid, with the ^1H CRAMP spectrum on one axis and the ^{13}C CP MAS spectrum on the other.⁶⁶ This showed that a broad band in the CRAMP spectrum could be assigned to a mixture of contributions from alkyl and *O*-alkyl structures, with the latter offset to slightly higher chemical shifts.

Despite this progress, the problem of separating overlapping signals remains one of the greatest challenges in NMR studies of agricultural and soil samples.

1 INTRODUCTION

Coal has been used as an important source of fuel for thousands of years, but it is a complex, heterogeneous fuel which is difficult to burn or process without serious environmental implications. Coals can vary significantly among different geographic areas in important properties such as rank, ash, sulfur and nitrogen content, mineral impurities, and maceral constituents. Substantial worldwide attention is being focused on more efficient and cleaner methods for utilization of this important energy resource.

The wide heterogeneity of coal has made it difficult to characterize and to correlate its structure. Evidence exists that differences in geological histories and maceral constituents affect coal chemistry and technological applications of coals, since coals of the same apparent rank but of different geological history can exhibit a variety of physical and chemical properties. Coal structure varies with recognizable geological and geochemical features which affect its reactivity. The variations in the geochemical history and the complexities of the macromolecular structure of coal further confound a clear understanding of the complex nature and interrelationships among coals.¹

Our understanding of the details of coal structure has improved markedly over the last decade. Coal is now believed to be a heterogeneous mixture composed of a macromolecular network of varying degrees of cross-linking within the macromolecular phase with a smaller molecular phase imbibed or associated with this network. A major portion of the credit for the present state of knowledge of the general characteristics of coal structure can be traced to studies that employed NMR spectroscopy. It is interesting to observe that NMR was first applied to the study of coals in 1955,² only nine years following the discovery of the NMR phenomenon in bulk matter. These first NMR observations employed broadband ¹H techniques which, in the absence of means to reduce the large proton dipole-dipole interactions, produced very broad bands in fossil fuel related materials. In 1968 Haeberlen and Waugh³ demonstrated that the hydrogen dipole-dipole interaction could be significantly reduced by averaging in spin space via a multiple pulse approach⁴ rather than attempting to spin the sample mechanically at very high MAS rates in order to achieve the same results. In the mid-1970s Schnable⁵

and Gerstein et al.^{6,7} demonstrated that if the sample is spun simultaneously about the magic angle then the chemical shift anisotropy (CSA) as well as the inhomogeneous heteronuclear dipolar interactions are simultaneously averaged. Hence, much narrower peaks are obtained with this experiment which Gerstein named CRAMPS. The proton CRAMPS experiment was first applied to coals by Gerstein in 1981.⁸ The CRAMPS experiments have been especially useful as a probe to study the 'mobile phase' present in coal structure wherein solvents such as perdeuterated pyridine are imbibed into the parent coal.⁹⁻¹³ The reduction in proton NMR linewidths is attributed to motional narrowing and to reduction of bulk and molecular susceptibility anisotropies by partial mobilization of certain structural moieties in coal caused by disruption of hydrogen bonds and other noncovalently bonded structural units.

As early as 1966 the first ¹³C NMR spectra appeared of materials derived from coal.¹⁴ Broadline ¹³C NMR spectroscopy was first applied to whole coals in 1971 to confirm the high aromaticity of anthracite.¹⁵ Significant improvements in resolution began to emerge five years later¹⁶ with the application of the cross polarization technique followed by applications of magic angle spinning to coal.¹⁷ In 1979 Opella and Frey¹⁸ introduced the concept of the dipolar dephasing experiment which discriminates between nonprotonated and protonated carbons by means of the effective C-H dipole-dipole interaction. Alemany et al. studied the characteristics of the dipolar dephasing experiment on model compounds¹⁹ and then demonstrated the utility of this experiment in a careful study of an Illinois No. 6 coal.²⁰ Work by Wilson,²¹ Murphy,²² and Gerstein²³ and their co-workers has verified the value of dipolar dephasing experiments in the study of coal. The data derived from the techniques described, together with others to be described in subsequent sections, have been extremely valuable in probing the general structural features of coals and have greatly enhanced the usable knowledge base for improved coal utilization.

2 EXPERIMENTAL TECHNIQUES

Since the organic constituents of coal are composed primarily of hydrogen and carbon with smaller amounts of oxygen, nitrogen, and sulfur (typical elemental compositions of a lignite, high volatile bituminous, and anthracite coal are C₁₀₀H_{78.9}N_{1.4}S_{0.4}O_{22.7}, C₁₀₀H_{76.2}N_{1.7}S_{0.4}O_{6.1}, and C₁₀₀H_{17.5}N_{0.7}S_{0.2}O_{1.5}, for the Beulah-Zap, Pittsburgh No. 8, and Buck Mountain, respectively) (see Section 5), NMR experiments have focused primarily on ¹H and ¹³C applications. While ¹H NMR experiments (particularly the CRAMPS applications) have added valuable insight for coal structural studies, the major area of interest has been in the elucidation of the carbon skeletal structure since many of the questions regarding the physical and chemical properties can be addressed from a clear understanding of the details of the carbon backbone and associated functional groups. Carbon-13 NMR spectroscopy has become one of the premier tools in organic structure analysis due to the relationship between the local electronic environment of the carbon nucleus and the ¹³C chemical shift and, hence, the use of ¹³C NMR techniques has become essential for the study of solid carbonaceous materials such as coal chars, pitches, and geochemical materials in general.

2.1 CP MAS and Isotropic Shifts

The combination of cross polarization and magic angle spinning has been used to obtain high-resolution NMR spectra from solids for many years. Magic angle sample spinning at a rate greater than the chemical shielding anisotropy (CSA) of the carbon nuclei will average the principal values of the chemical shift tensor (δ_{11} , δ_{22} , δ_{33}) to the isotropic chemical shift value. Linewidths obtained by CP MAS experiments are typically of the order of 1–2 ppm in simple organic compounds but relaxation effects (T_2), anisotropy in bulk susceptibility, crystallinity, and solid state effects can considerably broaden the individual spectral lines. In some cases one may observe multiple lines due to lattice structures that contain multiple structures per unit cell or crystal lattice effects that impose a preferred conformation which breaks the local symmetry. In general, the solid state isotropic chemical shifts are similar to those in solution and the appropriate chemical shift/structure relationships developed in solution studies may be used to interpret solid state CP MAS spectra.

The Utah group^{24,25} illustrated the relationship between isotropic chemical shifts and the CP MAS spectra of coals. While coal spectra are characterized by banded structures in the aliphatic and aromatic regions, it is evident from the bandshapes and shoulders on these bands that structural information is available beyond that obtained from aromaticity considerations only. Gerstein demonstrated that isotropic chemical shifts could be used to look .. ‘beyond just aromaticity; chemical functionality’.²⁶ An example of the diversity of the ^{13}C NMR spectra of coals is presented in Figure 1 for a series of coals of ranks ranging from lignite through anthracite.

Solum et al.^{27,28} have used a rather detailed isotropic chemical shift distribution together with dipolar dephasing data to obtain 12 structural parameters for the coals contained in the Argonne Premium Coal Sample Bank. Wilson et al.²⁹ and Hatcher et al.³⁰ have used isotropic ^{13}C NMR data to propose chemical transformation pathways for coal precursors, while Hatcher et al.³¹ have used such data to construct a three-dimensional computer simulation of coal formation from components of plant precursors. Hence, CP MAS chemical shift data have had a major impact in geochemical applications in general and fossil fuels in particular.

2.2 Shielding Tensors and 2D Methods

The CSA is a reflection of the interaction of the electronic environment of the nuclei with the external magnetic field. Depending on the orientation of a given molecule in the field, a different value of the chemical shift is observed. If the sample simultaneously exists in all possible orientations (as in the case of a powder sample), a superposition of all the possible shift values for the nuclei in the molecule is observed. The frequencies obtained from the breakpoints or discontinuities of this powder pattern are the principal values of the chemical shift tensor. For a ^{13}C nucleus in an anisotropic environment, three distinct values are observed, and these values correspond to the three elements (δ_{11} , δ_{22} , δ_{33}) found as the diagonal elements of the chemical shift tensor. From the study of single crystals, both the principal values of the shift tensor and their orientation in the molecular framework can be determined.

Figure 1 CP MAS spectra of the Argonne Premium Coals plus the Buck Mountain anthracite (PSOC-1468). The data were acquired as described by Solum et al.^{27,28} Coal rank increases from bottom to top in the figure

Single crystal studies of aromatic compounds show that δ_{33} is always perpendicular to the plane of the aromatic ring³² and its value in the aliphatic region reflects its independence of the π system. The other two tensor components, δ_{11} and δ_{22} , are oriented in the plane of the aromatic system. Theoretical studies have placed δ_{11} nearly perpendicular to the C–C bond with the largest π -bond order in all of the polycondensed aromatic hydrocarbons studied.³²

Orendt et al.³³ have provided a brief description of experimental methods for studying chemical shift tensors in model compounds and coals. Extracting principal values from powders is extremely difficult due to the inherent low resolution of the experiment. Hence, principal values can normally be obtained only for very simple compounds or compounds of high symmetry containing only two to three tensors. The variable angle sample spinning (VASS) technique improves the resolving capacity to only three to four tensors.³⁴ Yet the information provided by CSA data is very valuable in the study of small molecules and even relatively large systems such as naphthalene, pyrene, hexahydropyrene, pyracene, and coals.^{33,35} The data obtained on such systems have demonstrated that the shape of the tensor patterns can be used to distinguish different types of carbons in an environment where spectral overlap might preclude identification based on isotropic chemical shift information. This is particularly advantageous for coal due to spectral overlap in both the aromatic and aliphatic regions. Due to the large range in the principal values of the chemical shift tensors in aromatic carbons, an effort to obtain such data on coals is most fruitful since the carbon backbone of coals is dominated by aromatic species.

Table 1 Average Chemical Shift Tensor Values for Aromatic Carbons^a

Carbon type	δ_{11}	δ_{22}	δ_{33}	δ_{av}
Protonated (75)	207 $\pm$ 22	146 $\pm$ 19	18 $\pm$ 12	124 $\pm$ 11
Substituted (21)	226 $\pm$ 11	165 $\pm$ 15	23 $\pm$ 14	138 $\pm$ 8
Phenolic (16)	227 $\pm$ 16	163 $\pm$ 9	72 $\pm$ 3	154 $\pm$ 6
Condensed (7)	205 $\pm$ 2	195 $\pm$ 2	-72 $\pm$ 5	133 $\pm$ 2

^aThe numbers in parentheses following the carbon type are the number of measurements considered in the analysis. Errors represent standard deviations of available data. All values are given in parts per million. The first three lines of data are from T.M. Duncan, 'A Compilation of Chemical Shift Anisotropies', Farragut Press, Chicago, IL, 1990, p. C-5. The data on condensed carbons come from data obtained at the University of Utah.

For convenience, the aromatic carbons in coal can be grouped into four categories: protonated, substituted (having an alkyl group substituent), phenolic (having a hydroxy or ether substituent), and bridgehead or condensed. Presently available chemical shift tensor data on these types of carbons are summarized in Table 1 while Figure 2 portrays the ideal lineshapes for the four types of carbon of interest. These ideal lineshapes were obtained by tabulating literature values for the shift tensor components for aromatic carbons in simple organic compounds measured by a variety of methods.³²⁻³⁷ These data have been used to study the aromatic structure in a fusinite maceral, two anthracite, and three bituminous coals.^{33,35}

A detailed description of methods for obtaining chemical shift tensors is contained elsewhere (see *Chemical Shift Tensors*). Hughes et al.³³ have used a static chemical shift-chemical shift correlation spectroscopy experiment (referred to as the 2D flipper experiment) to examine the chemical shift tensor patterns in a medium volatile and a low volatile bituminous coal. In a conventional 1D static solid state spectrum of coal, a large degree of overlap between aromatic and aliphatic signals occurs, whereas the 2D chemical shift-chemical shift correlation spectrum clearly separates the two spectral regions and exhibits the presence of multiple overlapping chemical shift tensors in both the aromatic and aliphatic regions of both samples. Furthermore, this separation of spectral regions allows for the determination of the aromaticity from a non-MAS spectrum. The aromaticity values (f_a) are 0.78 for the Upper Freeport and 0.87 for the Pocahontas No. 3 coals compared with values of 0.81 and 0.86 determined by CP MAS experiments.^{27,28}

In an effort to address the problem of spectral overlap many 2D techniques have been developed to obtain a spectrum with an isotropic shift along one axis and a stationary or slow-spinning sideband powder pattern along the other. One such technique, the triple echo magic angle turning (triple echo MAT) experiment (see *Magic Angle Turning and Hopping*), has proven to be especially effective for studying model compounds and has been used to examine a number of coals, including those in the Argonne Premium Coal Sample Bank,³⁸ a naphthalene-derived pitch, a semi-anthracite, and an anthracite coal.³⁹ The chemical shift tensor patterns taken at various isotropic shift values in coals clearly exhibit the presence of the characteristic shapes of the chemical shift tensors of protonated, substituted, phenolic, or bridgehead carbons and, hence, one is able to distinguish different types of carbons in broad spectral regions where it is impossible to

**Figure 2** Ideal tensor patterns and average isotropic shifts for the four types of aromatic carbons in coal: (a) protonated, (b) alkyl substituted, (c) condensed or bridgehead, and (d) phenolic

distinguish individual lines. An example of the deconvolution of overlapping lines is given in Figure 3, where the slice taken at an isotropic chemical shift value of 124 ppm is shown for Pocahontas No. 3 low volatile bituminous coal.⁴⁰

The simulation of the individual powder patterns for an axially symmetric aromatic tensor and an overlapping protonated tensor are compared with the experimental data in Figure 3. A modified version of the triple echo MAT experiment called PHORMAT (see *Magic Angle Turning and Hopping*), which incorporates rotor pulse synchronization, has been used in a blind comparison of the tensor principal values obtained from single crystal data in methyl α -D-glucopyranoside.⁴¹ The principal values for the six carbons in this model compound have an rms average distance of 0.57 ppm from the tensors determined from the single crystal data, while the estimated variation in the principal values of the tensors studied with the triple echo MAT experiment vary by approximately 2 ppm.⁴⁰ Hence, the principal values reported by the Utah group have been shown to represent faithfully the single crystal data within 2 ppm when the triple echo MAT experiment is used, and an error of 0.5–1 ppm is expected if the more precise rotor pulse synchronized PHORMAT experiment is used. A remarkably good correlation is also obtained between the carbon aromaticities (ratio of

Figure 3 Spectral slice taken at an isotropic chemical shift of 124.5 ppm from the triple echo MAT experiment on Pocahontas No. 3 coal obtained from the Argonne Premium Coal Sample Bank. The experimental data were simulated as the superposition of protonated and condensed (bridgehead) aromatic carbon tensor patterns, labeled theoretical, which is overlaid on the experimental trace

aromatic to aromatic plus aliphatic carbons) determined from variable contact time CP MAS data and the triple echo MAT experiment. This relationship is shown in Figure 4 for the coals in the Argonne Premium Coal Sample Bank, two anthracites and a methylnaphthalene-derived pitch (correlation coefficient $R^2 = 0.991$), demonstrating that the slow spinning triple echo MAT experiment does not lead to any apparent distortions of the structural components in coals.

3 DESCRIPTION AND CONSTITUENTS

3.1 General Nature of Coals and NMR Parameters

Coal is a complex sedimentary rock derived from plant remains. During the coalification process the accumulated plant material underwent differing degrees of chemical decomposition and depolymerization. These degradation processes formed peat which was subsequently transformed into coal of different ranks and properties based on sedimentary input, local environment, depth of burial, and local geological history. These various local conditions combined to produce a material that can be quite variable in terms of elemental composition and the nature of the inorganic materials incorporated into the coal material either as mineral inclusions or as chemically bound species. The elemental composition (particularly

Figure 4 Comparison of aromaticity values for the Argonne Premium Coals, two anthracite coals (PSOC-867 and PSOC-628), and a methylnaphthalene-derived pitch. The CP MAS data were obtained as described by Solum et al.^{27,28} while the MAT values were obtained from the triple echo MAT experiment (see *Magic Angle Turning & Hopping*)

hydrogen, oxygen, and carbon) of the organic material can be used in a general classification scheme for describing the rank of a coal which, in increasing order, is given as peat, lignite, subbituminous, high volatile bituminous, medium volatile bituminous, low volatile bituminous, semianthracite, anthracite, and meta-anthracite. This rank progression exhibits a general order where the atomic ratios H/C and O/C decrease with increasing rank.

The most uniform microscopic constituents of coal, whose morphologically preserved or repolymerized materials retain distinct characteristics, are known as macerals. A large number of macerals have been identified and named. All macerals, however, can be conveniently grouped into three major subdivisions; liptinite, vitrinite, and inertinite. The vitrinite group of macerals are thought to be derived from plant cell wall material and make up the majority (50–90%) of most North American coals. The liptinite group of macerals is derived from algae and/or the resinous and waxy parts of plants such as resin, spores, pollen, and cuticles. These materials make up 5–15% of most North American coals but can be considerably higher in other coals and in coals derived from unique depositional environments. These macerals are the most aliphatic and hydrogen-rich of all the maceral groups. The inertinite group of macerals is derived from degraded woody tissue, making up 5–40% of most North American coals, but in western Canada and all southern hemisphere coals the percentage can be considerably higher.

The carbon aromaticity, f_a , is an important parameter in the study of coal and coal-derived materials and is the most widely used NMR parameter for coal studies. The first serious applications of ^{13}C NMR experiments to coal were directed at determining the carbon aromaticity. While several investigators studied a wide range of coals, Maciel et al.⁴² and Gerstein et al.^{23a} were the first investigators to investigate systematically the aromaticity/rank relationship. Gerstein et al. compared ^{13}C NMR-derived aromaticities with those obtained

Figure 5 Carbon aromaticity, f_a , as a function of carbon content on a dry, ash-free basis

indirectly from graphical densities. The relationship between carbon aromaticity and rank (as derived from % carbon) is given in Figure 5. In NMR studies of macerals, the general trend in f_a values is liptinite < vitrinite < inertinite. Early studies by Maciel et al.⁴³ and Zilm et al.⁴⁴ helped to define the variations in aromaticity in the different maceral groups as well as the apparent differences in chemical functionality arising from differences noted in the isotropic shift/intensity distributions. More detailed NMR studies of maceral groups helped to refine the range of variations in aromaticities and chemical functionality.^{25,45,46}

The quantitative accuracy of the f_a values derived from CP MAS experiments has been questioned and this controversy is addressed by Botto et al.⁴⁷ (see *Fossil Fuels*). Orendt and co-workers have demonstrated that quantitative accuracy is obtainable if the CP MAS data are taken carefully with a variable contact time experiment and the data fitted to the proper model.²⁸

3.2 Structural Components

The description of coal as a macromolecular network is credited to van Krevelen⁴⁸ who proposed a gel/sol model. The tools of polymer chemistry have been applied to study coal and advanced characterization techniques such as ¹³C NMR have assisted in defining the parameters of the macromolecular structure of coals. The current model for coal structure consists of clusters of aromatic and hydroaromatic ring systems that are cross-linked such that domains exist which can, in some cases, undergo rapid reorientational motion. The argument that supports a cross-linked macromolecular network, other than the fact that the bulk of coals are not soluble in common solvents, is that coals swell by as much as 250% when brought into contact with appropriate solvents. The degree of reversibility is also consistent with a covalently cross-linked structure and rules out entanglements as the only associative force. Coals also display viscoelastic properties which are consistent with a macromolecular structure.

The type and characteristic of the second phase or component of coal is not as well defined as the macromolecular network, and has been the subject of extensive debate.⁴⁹ The 'mobile components' observed in proton NMR experiments have been shown to be complex and their relationship to a trapped molecular phase is yet to be completely resolved. Two views have been taken regarding the 'mobile protons' observed in ¹H NMR experiments. The first is that these protons can be attributed to molecules that are free to rotate in cages of the macromolecular network, and the second is that the mobile protons are associated with fragments of the macromolecular network capable of rotation due to single C–C or C–O bonds linking such fragments to the network. Jurkiewicz et al.^{12,50} have used proton CRAMPS techniques to examine carefully the nature of the mobile protons in coal by comparing the native Argonne Premium Coals with those imbibed with pyridine-*d*₅. In pyridine-saturated coals the aliphatic and aromatic protons are better resolved and more structural details are evident. In addition, imbibing the samples with pyridine dramatically changes the structural or dynamic characteristics of a coal. The CRAMPS data provide a rough correlation between proton mobilities and the extractable components of coal. Employing a careful pyridine extraction study, Fletcher et al.⁵¹ have studied the ¹³C NMR structural components of the extracts and residues from the Argonne Premium Coals and contrasted the subtle differences between the extractable and residual components in terms of cross-linking between aromatic clusters.

An excellent review of the molecular structure, chemistry, and existing structural models of coal (up to 1986) is given by Davidson.⁵² The early coal structure models proposed by Given and Weiser⁵³ and further refined by Shinn and Solomon⁵³ were based, in part, on available NMR data. From these models investigators attempted to construct an average or representative macromolecular structure of coal. In general, the information used for assembling a coal structure is molecular weight, aromatic cluster size, linkages between aromatic units, carbon aromaticity, elemental composition, as well as experimental results from chemical and thermal reactions. In order to explain the physical properties of coal and the thermal and chemical behavior of coal, network models have recently emerged^{54–57} and solid state NMR data have become indispensable in constructing models that describe coal behavior.^{51,54–57}

4 APPLICATIONS TO COAL SCIENCE

4.1 Refinements in Structural Detail

Gerstein suggested that ¹³C NMR spectroscopy could provide more information on coal structure than just aromaticity and demonstrated that one could use dipolar dephasing techniques to examine functional groups and estimate aromatic cluster size.²² Alemany et al.^{19–21} refined the functionality studies employing painstakingly acquired dipolar dephasing data. Solum et al.^{27,28} carefully employed a variety of experiments (i.e. dipolar dephasing, variable contact time experiments, and integrations of the ¹³C spectra over selected chemical shift ranges) to derive 12 structural parameters for the eight

Figure 6 (a) Aromatic carbon structure distribution of the Argonne Premium Coals; (b) structural distribution of carbons associated with oxygen in the Argonne Premium Coals; and (c) carbon distribution of the aliphatic region of the Argonne Premium Coals

Argonne Premium Coals as well as a large variety of other coals and coal-derived chars.^{51,56,57} The traditionally defined carbon aromaticity, f_a , is a sum of the contributions of all sp^2 carbons to an NMR spectrum. In coal samples it is assumed that ethylene groups are not present in any significant quantity. Hence, the f_a values are assumed to consist of aromatic plus carbonyl groups and these parameters have been redefined as f_a' and f_a^C , respectively. Employing lengthy dipolar dephasing experiments, the relative contributions of protonated and non-protonated aromatic carbons can be estimated as f_a^H and f_a^N , respectively. The nonprotonated aromatic carbons, f_a^N , consist of contributions from alkyl-substituted, oxygen-substituted (phenols and phenolic ethers), and bridgehead carbons, defined as f_a^S , f_a^P , and f_a^B , respectively. The aliphatic groups have been segregated by chemical shift ranges which can be used to approximate the contributions from methyl groups, f_{al}^* , oxygen-substituted alkyl carbons, f_{al}^O , and f_{al}^H , which is defined as the sum of all CH, CH₂, and nonprotonated aliphatic carbons. While these parameters are derived from chemical shift ranges that are known to contain some overlap with other functional groups, these approximations are reasonable and can be used to develop approximate model structures that

Figure 7 Plot of the mole fraction of bridgehead carbons, χ_b , versus C where C is the number of carbon atoms per aromatic cluster. The solid curve is for the combined model, the upper dashed curve is for the circular catenation model, and the lower dashed curve is for the primary catenation mode. (See Solum et al.²⁷ for details)

are consistent with other analytical data. The major structural parameters derived from the coals in the Argonne Premium Coal Sample Bank plus Buck Mountain anthracite are given in Figure 6. From a knowledge of the relative number of peripheral and bridgehead carbons, it is possible to estimate the average aromatic cluster size of coal samples.²⁷ The average cluster size model for coal is shown in Figure 7 and the range of average number of aromatic carbons per cluster (AC/CI) is given in Figure 8. This parameter has proven extremely useful in analyzing changes that occur during conversion and combustion processes.

If one defines the total number of ring attachments as the number of alkyl and oxygen substituents on the average aromatic cluster, it is possible to estimate the number of attachments per cluster. This number is between three and six for all coals studied but small variations in this parameter, defined as the cluster coordination number ($\sigma + 1$), are very important in explaining phenomena associated with coal structure, physical properties, and combustion behavior. The cluster coordination numbers for the coals previously described are given in Table 2.

4.2 Applications to Combustion and Pyrolysis Modeling

As previously discussed, the present model for coal structure is based on a network consisting of aromatic clusters of varying size connected by various types of bridging groups, and a simple schematic of the major types of structural elements that can be derived from NMR data is shown in Figure 9.

Figure 8 Aromatic cluster size of the Argonne Premium Coals and Buck Mountain anthracite, PSOC-1468

^aThe Advanced Combustion Engineering Research Center (ACERC) selected a set of standard coals for characterization and combustion testing and modeling. The 11 coals consist of the eight coals contained in the Argonne Premium Coal Sample Bank and three additional coals obtained from the Penn State Coal Sample Bank. Column headings are defined in the text.

^bAveraged over two or more sample vials.

A number of investigators have applied statistical methods to predict how such a network would behave when subjected to thermally induced bridge-breaking cross-linking and mass transport processes. The geometry of a network is described by its degree of branching. An unbranched linear network will have one bridge per ring cluster attaching it to the next cluster. Thus, each cluster has two attachments and is said to have a coordination number ($\sigma + 1$) of two. A highly branched network would have several bridges attached to it and a higher coordination number. When coal is heated, the connecting bridges can break and new bridges can form. The objectives of network models of coals are, given the geometry

Figure 9 Representative chemical structural units identified in ^{13}C NMR analysis of coal and coal chars

of the macromolecular network, to predict the concentrations of individual aromatic ring clusters (monomers) and linked clusters (oligomers of n clusters, ' n -mers') that are completely detached from the totally linked network, as a function of the number of unbroken bridges. By assigning an average or distribution of molecular weights to the ring clusters, the amounts of tar, extractables, liquids, or char can then be defined from the distribution of oligomer sizes. The application of network models appears to unify many observations of coal pyrolysis, including tar formation, extract formation, metaplast formation, fluidity, and solvent swelling behavior.⁵⁴

A major challenge to all network models is the acquisition of analytical data that describe the network with sufficient detail that the investigator is not required to make guesses or fit the experimental data in order to derive critical network parameters. Grant et al.⁵⁵ have demonstrated that the coal macromolecular structure can be modeled as a Bethe lattice and that this lattice structure can explain the nonlinear behavior associated with devolatilization processes of coals. The coordination number of the Bethe lattice, $\sigma + 1$, is a key element in predicting the lattice behavior, and this parameter is determined directly from NMR data as the average number of substituents on an average aromatic cluster. Four other essential parameters, P_o , BL , MW , and m_δ , can be derived from the NMR data of coals.

The fraction of intact bridges between clusters, P_o is calculated with the assumption that all nonbridging cluster substituents are terminated by a methyl group and can be estimated as

$$P_o = [(\text{attachments}/100\text{C}) - f_{\text{al}}^*]/(\text{attachments}/100\text{C}) \quad (1)$$

While it is recognized that aryl-aryl bridges and phenolic groups are present in relatively small amounts in most coals, these structural units cannot be easily derived from NMR data and, hence, this approximation neglects hydroxy and aryl groups as possible chain terminators. The remaining cluster attachments must be either aliphatic or ether bridges between different clusters or aliphatic loops between two adjacent carbons in the same aromatic cluster, i.e. a hydroaromatic structure such as exists in tetralin. The number of bridges and loops, BL , on a cluster is defined as

$$BL = P_o \times (\sigma + 1) \quad (2)$$

The mechanical properties of the network will be related to this parameter because BL is related to the cross-link density of the macromolecular structure. The average cluster molecular weight (MW), and the total mass of the attachments to the aromatic cluster (m_δ) are

$$MW = (\text{aromatic carbons/cluster} \times 12.011) / (f_{a'} \times \%C) \quad (3)$$

$$m_\delta = (MW - C_{\text{clust}} \times 12.011) / (\sigma + 1) \quad (4)$$

where C_{clust} is the average number of carbons per cluster. While these parameters fall within certain ranges (see Table 2), each coal is unique and must be modeled separately.

During coal devolatilization, both tar (defined as volatiles, other than water, that condense at room temperature) and gas (CH_4 , CO , CO_2 , H_2O , light hydrocarbons, etc.) are released and a residual char remains. Employing the NMR-derived parameters needed to model the macromolecular network of each coal, it is possible to predict the tar and total mass loss (tar plus gas) of a set of coals with reasonable accuracy, as seen in Figure 10, without the necessity of invoking fitting parameters.

The mass of attachments to the aromatic ring is directly related to the amount of gas liberated during coal devolatilization through thermal cracking of the side chains.⁵⁷ During the pyrolysis process the physical and chemical properties of the residual char are continually changing. Solum et al.⁵⁶ were able to follow the details of the release of tar and gas together with the evolution of char structure from a lignite (Beulah-Zap) and a high volatile bituminous (Illinois No. 6) coal during devolatilization. The NMR data were used to track the lattice parameters associated with average cluster size and cross-linking reactions. Under rapid heating conditions (10^4 K s^{-1}), the data demonstrate that Zap coal undergoes early cross-linking behavior due to the loss of carboxy groups whereas Illinois No. 6 exhibits a slower overall rate of cross-linking. It was further noted from the NMR data that the number of cluster attachments remained constant during mass release

during rapid pyrolysis at a temperature of 1250 K. However, near the end of the mass release the number of bridges and loops increased, suggesting that the coal lattice had begun to cross-link as tar release was terminated but as gas release continued. Under rapid heating but short resident time conditions in the reactor employed, the data exhibited little evidence of cluster size growth in the macromolecular structure. These data suggest that near the end of the devolatilization process cross-linking occurs at the same time as aliphatic carbons are released and the graphitization process does not occur under the conditions of the experiments performed. In the Illinois No. 6 coal, most of the mass loss occurred before the onset of significant changes in aromaticity. For the Zap coal, the changes in aromaticity occurred much earlier than for Illinois No. 6. The carbon skeletal structure of the final chars are similar for these two coals and Fletcher et al.⁵⁷ have reported similar results on a number of other chars even though the structure of the initial coals are quite different.

The physical properties of the macromolecular structure are related to the extent of cross-linking present. The NMR-derived bridges and loops parameter can be used estimate the degree of cross-linking that exists in coals and chars. An NMR cross-link index can be defined as

$$\text{NMR index} = (M_\infty - M_T) / (M_\infty - M_0) \quad (5)$$

where M_T is the number of bridges and loops per cluster at temperature T and the 0 and ∞ subscripts refer to the parent coal and the fully pyrolyzed char respectively.

Figure 11 compares the cross-link density obtained from the ^{13}C NMR data with that obtained from solvent swelling experiments.⁵⁷ These data clearly demonstrate that the functional form of the NMR cross-linking index is consistent with the normalized volumetric swelling index commonly used to study the cross-link structure in polymers. In the Beulah-Zap lignite, the number of bridges and loops increase with temperature, indicating that initial cross-linking has occurred at a relatively low temperature ($\sim 500 \text{ K}$) and progressive cross-linking occurs as the temperature increases. In the case of the Pittsburgh No. 8 coal, the NMR data suggest that the initial solvent swelling behavior is due to the breaking of labile bridges at moderate temperatures (500–600 K), which permits increased flexibility of the macromolecular network. At higher temperatures ($>700 \text{ K}$), the number of bridges begins to increase as the swelling of the coal decreases. Such behavior would be expected as a more rigidly cross-linked network developed. The NMR data confirm that low-temperature cross-linking occurs in low-rank coals and that cross-linking at moderate temperatures is observed in both bituminous and low-rank coals.

The preceding examples demonstrate that NMR spectroscopy provides a great deal of information on coal structure and is perhaps the premier analytical tool in coal studies despite the inherent difficulties in carrying out experiments and interpreting the quantitative nature of the data. Even so, data carefully taken can be used to assess differences that occur in coals and follow many processes associated with coal utilization. Ambiguity exists in extracting information from overlapping spectral bands in both the aromatic and aliphatic regions. However, promising new experiments, such as the triple echo MAT and PHORMAT, that take advantage of the information contained in the chemical shift tensors, will probably resolve

Figure 10 Comparison of predicted and measured tar and total volatiles yields for a wide range of coals. Data are for coals from the Argonne Premium Coal Sample Bank and from the Penn State Sample Bank for which NMR and pyrolysis data are available. (See Solum et al.⁵⁶ for details)

Figure 11 Comparison of the normalized volumetric swelling ratio (NVSR) for Beulah-Zap lignite and Pittsburgh No. 8 with the ^{13}C NMR index derived from the number of bridges and loops present in the parent coals and the pyrolysis chars. (See Solomon et al.⁵⁴ for details)

some of these ambiguities, particularly those associated with the aromatic region of the spectra.

5 NOTE

Beulah-Zap and Pittsburgh No. 8 are from the Argonne Premium Coal Sample Bank, while the Buck Mountain anthracite is available from the Penn State Sample Bank as PSOC-1468.

1 INTRODUCTION

Energy¹ is an important commodity because it affects our lives in many ways. In the past, a direct relationship had been drawn between energy consumption and economic growth. Advancement in economic growth was shown to have a favorable impact on the quality of life in economically advanced societies by fostering better health and educational services, a robust industrial base with which to sustain future development, and various forms of labor-saving devices for common use. Often concerns about the negative impacts from economic growth, such as pollution, overpopulation, and crime have been neglected by nations striving to improve their economic status.

In the rapidly changing world of the last 20 years, however, there have been escalating demands placed on global energy resources. An ever-increasing number of developing countries have competed for the existing energy supply. Environmental issues have become the highest priority in guiding the utilization of global resources. While traditional 'old-world' fuels such as wood, agricultural products, and animal dung are still in use around the globe, they remain effective sources of energy only for less developed societies. Alternative energy resources in the form of geothermal and hydroelectric power are limited throughout the world, while renewable resources such as solar, wind, and tidal have been slow to develop on a large commercial scale. Development of nuclear energy, once heralded as the answer to meet the future global energy demands into the next millennium, has been severely curtailed because of apprehension about radioactive release into the environment and problems in storage of high level radioactive wastes. Consequently, a greater burden of world energy demands over the past 20 years has centered on fossil fuels. With increasing demands on supplies worldwide, fuel quality has diminished significantly. In addition, utilization of fossil fuels as a carbon source for the production of bulk and specialty chemicals, and of high technology polymer blends and composites may be almost as important economically as their use as an energy source.

Fossil fuel energy resources include coal, peat, petroleum, oil shale, tar sands, and natural gas. Total world resources of coal are 15.1×10^{12} ton; total world production is estimated to be 3.0×10^9 ton per year. The importance of coal as a resource is that, despite having greater problems with production, transportation and utilization compared with oil and gas, it

represents a vast resource to meet energy demands well into the future (for more than 1000 years). World resources of peat, being far less utilized than the other fuels, is estimated to be only 0.2×10^{12} ton. Estimates of the reserves and resources of petroleum, having received considerable attention because of concern over their eminent depletion globally, are on the order of 0.3×10^{12} ton, of which about 0.1×10^{12} ton are proven reserves. Worldwide oil production is about 4×10^9 ton per year. Enhanced oil recovery strategies have added approximately an additional 0.1×10^{12} ton to the estimate of total recoverable resources of petroleum. Tar sands are fairly localized throughout the world, with estimated reserves of only 0.03×10^{12} ton. On the other hand, oil shale deposits are widely distributed geographically and represent a potentially enormous resource, with estimates ranging between 100×10^{12} and 500×10^{12} ton of potential oil. Limitations for the commercialization of this vast energy resource are the large-scale operations required for production and hence prohibitive investment costs, and the severe environmental problems that would be created by the massive excavation of natural lands and subsequent disposal of enormous quantities of solid waste. Natural gas, with proven reserves similar in energy equivalence to those of petroleum, has the advantage of being the cleanest of the fossil fuels; however, transportation costs of this commodity between continents are high unless supplies can be reached economically via pipeline.

Applications of NMR spectroscopy to the study of fossil fuels have experienced extraordinary growth since the inception of the technique in 1946.²³ Early experiments focused on the application of broadband ¹H NMR spectroscopy to petroleum, oil shale, and coal research. High-resolution liquid state ¹H NMR proved to be an extremely useful structure elucidation tool for fuel extracts and solubilized conversion products in subsequent years. However, NMR did not flourish as a celebrated technique for fossil fuel characterization until the 1970s. The growth of the technique was brought about by several factors: (1) integration of computers with instrumentation in the late 1960s enhanced data acquisition capabilities considerably; (2) introduction of Fourier transform methods paved the way for the development of pulsed NMR spectroscopy, which made detection of less sensitive nuclei more routine, and spawned a wide variety of pulsed techniques for sensitivity enhancement, relaxation measurements and multidimensional NMR studies; and (3) the oil embargo of 1973–74 and the Organization of Petroleum Exporting Countries (OPEC) incident in 1979 catalyzed abrupt increases in the price of petroleum, reversing the trend of cheap and abundant energy supplies that had lasted over the past 100 years. This incident prompted general concern over the availability of energy resources in the future and, as a consequence, stimulated growth of basic and applied research in the area of fossil fuels to seek alternate forms of energy. Nearly two decades of intensive research in NMR characterization of fossil fuels ensued.

2 APPLICATIONS TO COAL SCIENCE

Coal⁴ is considered to be a heterogeneous organic rock and is typically black in color, although geologically younger deposits can range in color from brown to brownish red. It is formed by the accumulation of plant debris which has been

altered over geological time by the action of biological, chemical, and physical (heat and pressure) degradation processes. The relative quantities of remaining plant parts, and the degree of their thermal maturation and degradation result in coals with varied properties. Coals may be classified as banded (humic coals) or nonbanded (cannel or boghead coals), are hard or soft, or can vary in rank from brown coal, through lignite, subbituminous, bituminous to anthracite. The degree of thermal maturation of plant matter, or coalification, is referred to as *rank*.

The evolution of coal, the enormous variation found in its composition, its microheterogeneity, and its differentiation toward chemical reactions suggest that coal is a complex mixture of compounds. While this is true, however, there is some order to its inherent, overall structure. There are microscopically discrete, optically homogeneous aggregates of organic materials derived from various plant parts that constitute coal. These individual domains are referred to as *macerals*.^{5,6} There are three major maceral groups, each having their own distinct set of properties and selective chemistries. The most abundant of the macerals found in US coals is *vitrite*, which is derived from woody tissue of plants and is a largely lignin based polymer. The group of macerals called *liptinite* may be derived either from waxy leaf cutin, parts of spores and pollen, or algal bodies. This group of macerals tend to be composed of highly aliphatic material. The last maceral group, *inertinite*, named for its relative unreactivity in most chemical reactions, is thought to be derived from material that has undergone extensive oxidation or that is a form of fossilized charcoal derived from primordial forest fires. The inertinite macerals have a high degree of aromatic character.

Apart from the organic components, there may be substantial quantities of water and mineral matter present in coal. The minerals can be varied and also rather complex in composition; hydrated aluminosilicates, clay minerals, quartz, sulfides, sulfates, pyrite and carbonates have been identified, to name a few. The main elemental constituents of coals, therefore, are carbon, hydrogen and oxygen, with varying amounts of nitrogen and sulfur, and lesser amounts of silicon, calcium, aluminum, iron, magnesium, sodium, and other trace elements. Given this diversity of chemistry and elemental composition, coals have been a rich source for study by NMR techniques.

2.1 Structure Characterization

2.1.1 Liquid State NMR

The first published account of high-resolution ^1H NMR of a coal liquid, or soluble reaction product, appeared in 1959.⁷ This first ^1H spectrum (Figure 1) of a coal asphaltene recorded in carbon disulfide at 125°C demonstrated that the technique could readily distinguish three magnetically inequivalent types of proton nuclei in the sample, and confirmed that few polynuclear aromatic structures were present. This was the first definitive structural information obtained on a fossil fuel material. Two years later, the first liquid state ^1H NMR spectrum of a coal extract was reported. Since that time, numerous workers have reported on similar studies involving

Figure 1 The first proton NMR spectrum of an asphaltene in carbon disulfide at 125°C. Recorded by J. N. Shoolery, H. E. Weaver, and R. C. Jones at Varian Associates

coal extracts and have demonstrated the utility of the technique for analyzing the hydrogen distributions in these materials.⁸

In 1960, Brown and Ladner⁹ were the first to demonstrate that the hydrogen distribution in carbonaceous fuels determined by ^1H NMR could be used to infer information about the carbon skeleton. Initial experiments were performed on a series of vacuum carbonization products from coals. The method used information from the ^1H NMR spectrum and carbon and hydrogen elemental analysis to determine several important structural parameters, including the fraction of aromatic carbon (f_a) of the sample. The fraction of carbon aromaticity was defined as that fraction of the total number of carbon atoms which are aromatic, $f_a = C_{ar}/C_{tot}$. The normalized intensities of the types of hydrogen were determined from integration of the proton spectrum to calculate the carbon aromaticity using the equation:

$$f_a = \left[(C/H) - (H_\alpha/x) - \frac{(H_\gamma + H_\beta)}{y} \right] / (C/H) \quad (1)$$

where C/H is the atomic ratio of carbon to hydrogen from elemental analysis data; x and y are the average number of hydrogen atoms per α -alkyl group to an aromatic ring and the remaining alkyl groups, respectively; and H_α and $(H_\gamma + H_\beta)$ represent the normalized integrated intensities of the α -alkyl hydrogen atoms and other hydrogen atoms, respectively. From this basic equation can be deduced other key structural parameters, such as the degree of aromatic ring substitution, i.e. that fraction of peripheral aromatic carbon atoms bearing substituent groups, and the atomic H/C ratio for the hypothetical aromatic ring system, which provides an estimate of the average size of the polycondensed aromatic rings.

In subsequent years, numerous researchers applied the Brown-Ladner equation to a wide variety of coal-derived liquids, including coal extracts, autoclave asphaltenes, carbonization oils, solvent-refined coals, coal tar pitches, and coal liquefaction products. However, there were several assumptions which had to be made in the application of the

Brown–Ladner equation, and the results obtained often depended on assumed values for x and y . For most fossil fuels, x and y were assumed to be 2, which was the same as suggesting that the average aliphatic carbon structure in these materials represented a methylene group. There was also the problem with accurate integration of the H_α and $(H_\gamma + H_\beta)$ protons because of severe overlap of the resonance lines. Derivation of the remaining parameters from the Brown–Ladner approach necessitated accurate deconvolution of the phenolic protons from aromatic protons, which was not always possible because of solvent-induced shifts of the hydroxyl resonances. Nevertheless, the approach was used to estimate the chemical structure parameters for many fossil fuels prior to the advent of high-resolution ^{13}C NMR.

The first high-resolution ^{13}C NMR spectrum of liquid products was published as early as 1966 using computer-assisted techniques. However, it was not until the mid-1970s, after the development of Fourier transform methods, that ^{13}C NMR of liquid and soluble materials from coal became routine.⁹ The first studies focused on comparing aromaticity data obtained directly by ^{13}C NMR with those estimated from the Brown–Ladner treatment of the corresponding ^1H NMR spectra. Several laboratories reported generally good agreement; for example, one correlation of ^1H and ^{13}C NMR data for five coals of different rank, coal tar pitches, coal carbonization oils, coal-derived asphaltenes, and products from five different liquefaction processes is presented in Figure 2.¹⁰ For the case of low boiling coal-derived oils, poor agreement was found because these materials tended to have shorter aliphatic chains, and hence the estimate for the ratio of aliphatic hydrogen to carbon (y in the Brown–Ladner equation) should have been greater than 2. Similar arguments were made for highly aromatic pyrolyzate products, in which there were high amounts of methyl substituents.

Later work focused on the assignment of chemical shift values to ^{13}C spectra of coal liquids. Efforts were made not

only to assign chemical shifts to various carbon functional groups in samples, but also to estimate the relative abundances of these groups. Inference was made for a relationship between ^1H and ^{13}C NMR data on the same sample, leading to the idea that complementary information from both techniques could lead to detailed structural characterization of complex, multicomponent fractions of coal liquids. Thereafter, numerous separation methods and other spectroscopic techniques were combined with characterization by ^1H and ^{13}C NMR to provide detailed structural profiles of individual components in complex coal mixtures.

One of the cornerstones of structural analysis methods has been the information provided by NMR, and there have been many practices of presenting the data. Three approaches that have frequently been used are: characterization by the formulation of structural parameters; characterization by the construction of average, or representative, molecular structures; and characterization by functional group analysis.¹¹ The first approach is considered by many to be limited because estimation of numerous parameters often relies on assumptions about molecular structure, and the average parameters calculated are not guaranteed to represent actual structures in fuel liquids. The use of an average structure, or model, to represent the system is flawed by the latter drawback. The advantage of the functional group analysis approach is that, by definition, it is chemical functionalities that govern the overall chemical and physical behavior of these complex molecular systems.

Functional group analysis has been applied in several laboratories to describe coal extracts and soluble reaction products.¹¹ The initial step in the process was to propose a set of functional groups that described the structure of the complex mixture. The concentrations of this selected set of functional groups were subsequently related to experimental data through a sequence of equations, where the effects of known stoichiometry are taken into account. In general, a set of equations can be written:

$$\sum_{j=1}^n A_{ij} |y_j| = b_i \quad (i = 1, \dots, m) \quad (2)$$

where y_j ($j = 1, \dots, n$) represents the unknown functional group concentrations, b_i ($i = 1, \dots, m$) represents quantities from experimental data, and A_{ij} represents the stoichiometric coefficients. The summation defined a range of possible solutions and a best fit was selected computationally through a minimization procedure by assuming that the distribution of atomic species among the functional groups is equally probable.

These methods have been tested on known mixtures and were subsequently used to characterize complex coal liquids. Utilizing data from NMR and elemental analysis gave fair estimates of molecular composition; incorporating data from mass spectrometry improved the results considerably. Characterization of separated fractions of coal asphaltenes derived from solvent-refined coal heavy distillate and supercritical gas extracts from two different coals provided information on the hydroaromatic content, distribution of heteroatomic functional groups, and nature of the polycondensed aromatic rings structures. In addition, these same methods have been used to reliably predict the thermophysical properties of liquid fuels,

Figure 2 Comparison of proton (f'_a) and carbon (f_a) aromaticities for materials derived from coal; H-coal, solvent-refined coals, COED, and Synthoil are liquefaction processes

by utilizing group additivity principles and the idea of continuous thermodynamics.

Numerous studies have centered on the use of conventional solution state NMR techniques to study the heteroatomic functional groups in coal-derived liquids, principally those containing oxygen, nitrogen and sulfur.¹² Regions within the ^{13}C NMR spectra of coal asphaltenes and coal-derived oils were examined and assigned to carbonyl groups, aromatic ethers and phenols, aliphatic ether groups, and nitrogen groups. Other investigations have employed derivatization methods to specifically 'tag' functional groups in combination with NMR analysis. Several approaches have been attempted. These include: either acetylation or reductive alkylation followed by ^{13}C NMR; trimethylsilylation with analysis by ^1H , ^{13}C and ^{29}Si NMR (see Figure 3); hexafluoroacetone adduction which can be analyzed by ^{19}F NMR; and phosphorylation followed by ^{31}P NMR. Direct analysis by ^{17}O NMR has facilitated examination of some fractions of coal liquids, leading to the identification of oxygen functional groups on the basis of their chemical shifts: for instance, alcohols, phenols and ethers; furans and carboxylic acids; esters; and ketones and aldehydes.

Given the complicated nature of the ^{13}C spectra of coal-derived liquids, several multipulse techniques based on the spin echo method were developed which allowed the selective examination of different carbon types.^{11,12} The gated spin echo (GASPE) or partially coupled spin echo (PCSE) pulse sequences were used to differentiate between aliphatic quaternary C and CH_2 , as one phase-related spin group, and CH and CH_3 as the other. The same techniques were also applied to obtain edited aromatic carbon spectra, for which the distinction between quaternary and tertiary aromatic carbon atoms could readily be made. The spin echo broadband off-resonance decoupling (SEBBORD) technique was used to differentiate further between quaternary and CH resonances on the basis of broadening of the CH resonances. Later, with the development of polarization transfer pulse methods, the use of either INEPT or DEPT sequences allowed separation of the entire carbon spectrum, into quaternary C, CH, CH_2 and CH_3

Figure 3 A typical ^{29}Si NMR spectrum of a coal liquid derivatized with trimethylsilyl chloride

resonances. Utilization of two-dimensional J -resolved and ^1H - ^{13}C COSY experiments on coal liquids, however, has met with limited success.

2.1.2 Solid State NMR

The earliest report on the use of broadband ^1H NMR in coal research was published in 1955 by Newman et al.¹³ However, apart from demonstrating that the NMR experiment was feasible on such materials, little chemical information was gleaned from this original work. It was more than 20 years later, in 1976, when the first solid state ^{13}C NMR spectra appeared in the literature,¹⁴ utilizing then recently developed CP methods for sensitivity enhancement together with strong proton decoupling.¹⁵ These initial ^{13}C spectra, recorded for four coal samples of different rank, are shown in Figure 4. It was the first time that coal structure was determined by a direct method for whole coals in their native state. Less than a year later, MAS with respect to the static magnetic field was used in combination with CP and proton decoupling to produce the first high-resolution solid ^{13}C CP MAS spectra of coal.¹⁶ This constituted a major breakthrough in the field; removing broadening effects arising from both CSA and ^1H - ^{13}C dipolar interactions produced isotropic resonance lines and facilitated the analysis of different carbon functional groups in coals. Also during 1977, MAS was combined with multiple pulse methods to produce the first high-resolution ^1H CRAMP spectra of whole coal samples.¹⁷ The technique facilitated analysis of aromatic and aliphatic proton distributions of coals in their native state.

Applications of solid ^{13}C CP MAS and ^1H CRAMP spectroscopy in coal structure determination have been reviewed extensively.^{12,18-22} Early ^{13}C CP spectra of coals (see Figure 4) exhibited two broad, overlapping resonance bands

Figure 4 CP ^{13}C NMR spectra of coals of increasing rank

estimate the fraction of substituted and bridgehead aromatic carbon atoms (f_{s+b}), and the number of quaternary aliphatic carbon atoms in these systems. Attempts to estimate the average cluster size of the aromatic rings from these data has had the caveat that it has been impossible to assign aromatic substituted and bridgehead carbon atoms with confidence because of severe overlap of the resonances. Nevertheless, interrupted decoupling solid state NMR has provided valuable insight into the nature of coal as a macromolecular material, and the technique has been used to explain some of the chemistry occurring upon its treatment under a variety of conditions.

Interrupted decoupling has also been employed with detection by CRAMPS to enhance the resolution of solid state proton spectra of carbonaceous materials.²² Analogous to the carbon version of the experiment in CP MAS spectroscopy, a dephasing period is inserted between the initial $\pi/2$ pulse that places the proton magnetization in the transverse plane and initiation of the multipulse decoupling sequence used for detection. The technique has been used on pyridine-sorbed coals and has provided selectivity of protons on the basis of molecular mobility.²²

Mathematical manipulation has been employed to enhance the resolution of solid NMR coal spectra.¹⁸ The several methods that have been implemented include: (1) convolution difference spectroscopy, which uses a filtering function composed of two exponentials and an adjustable weighting constant; (2) Gaussian multiplication, which has been used to improve resolution on the basis of lineshape modification; and (3) a variety of curve and Fourier deconvolution methods, for which the usual practice has been to fit mathematically a broad band of unresolved resonances to a series of peaks that are varied according to frequency position, lineshape, linewidth, and intensity.

Resolution enhancement in these systems has also been achieved based on carbon and proton relaxation time differences in CP MAS experiments.¹² Differentiation of carbon atoms in coals has been accomplished on the basis of differences in ^1H – ^{13}C polarization transfer rates R_{CH} , proton rotating frame spin–lattice relaxation rates $R_{1\rho}^{\text{H}}$, and carbon spin–lattice relaxation rates R_1^{C} .

Chemical derivatization techniques in conjunction with solid state ^{13}C NMR have been used to highlight the reactive oxygen functional groups, such as phenols, aliphatic alcohols and carboxylic acids. Acetylation¹² was employed to target specifically hydroxyl groups in coals and could be monitored by the introduction of additional carbonyl and methyl resonances in the solid reaction products. Comparing integrated signal intensities of the introduced acetyl resonances with those of native C–O gave estimates on the amounts of hydroxyl versus ether groups. The combined use of selective alkylation with ^{13}C -enriched methyl iodide and solid state ^{13}C NMR has also facilitated the assignment of methyl carboxylates, unhindered aryl methyl ethers, and hindered aryl methyl ethers in coals^{25,26} and isolated coal macerals.²⁷

Solid state NMR spectroscopy has seen limited applications to the study of mineral phases in coals. The first application focused on the use of ^{29}Si and ^{27}Al NMR to characterize mineral concentrates obtained by low temperature ashing of coals in order to obtain information on their mineralogy.²⁸ Silicon spectra allowed the identification of silicate resonances from quartz and clays, while aluminum spectra provided

information on the tetrahedral and octahedral coordination sites which allowed discrimination between kaolinite and illite clays that were present in the concentrates. A subsequent study²⁹ on mineral residues obtained from coal flash pyrolysis indicated that ^{29}Si and ^{27}Al spectra were broad because of the presence of paramagnetic species; however, the spectra were sufficiently resolved to detect the thermal transformation of kaolinite to quartz and mullite with increasing pyrolysis temperature. Characterization of the layer silicate minerals in the suite of Argonne Premium coals was carried out by using sink-float techniques to isolate mineral concentrates in combination with ^{29}Si and ^{27}Al NMR.³⁰ CP MAS and VAS techniques were employed to distinguish between the various clay minerals; quartz, kaolinite and smectite clays could readily be identified. Tetrahedral/octahedral aluminum ratios were determined for the coals, and the observation of increasing tetrahedral aluminum content with coal rank indicated there was a parallel between the diagenesis of the organic and inorganic matter in the coals.

2.1.3 Determination of Physical Structure

Solid state NMR spectroscopy has been applied extensively to the study of complex molecular dynamics in synthetic polymers. However, such investigations of coals have been limited. Work in this area has been hampered by the complex nature of coal. Interpretation of nuclear relaxation, which underlies the study of molecular motion, is complicated by the existence of discrete heterogeneous domains in coals and by relatively large quantities of paramagnetic centers which are present either in the form of paramagnetic inorganic ions or as organic free radicals.

To date, an overwhelming majority of papers dealing with relaxation measurements on coals has focused on the study of ^1H NMR spin–lattice relaxation times both in laboratory (T_1) and rotating ($T_{1\rho}$) reference frames. Early ^1H NMR measurements^{31–34} indicated that proton T_1 times in coals can either display single exponential or nonexponential relaxation behavior. The observation by Yokono et al.³³ that T_1^{H} varied linearly with the square root of resonance frequency for several bituminous coals was consistent with diffusion-limited relaxation to paramagnetic centers. Several laboratories^{34–37} later demonstrated similar behavior for a wide variety of evacuated coal samples. The work indicated that spin–lattice relaxation may be a fundamental property of coals themselves, and be independent of either their oxygen or moisture content. In two specific papers,^{37,38} the authors independently proposed that proton relaxation in bituminous coals was influenced by differences in molecular mobilities rather than by the relative concentrations of paramagnetic species.

A difficulty with the interpretation of spin–lattice relaxation of abundant proton spins in coals rests with the development of an experimental strategy to separate contributions from molecular mobility from spin diffusion of the magnetization to paramagnetic centers within different phase (maceral) boundaries. Three thorough investigations of ^1H NMR spin–lattice relaxation in coals^{39–41} have attempted to address this issue. The authors independently concluded that simple correlations of proton relaxation with other coal parameters was not easily realized. The presence of residual amounts of molecular oxygen in evacuated samples and the effects of different concentrations of unpaired electrons within different domains in

coals were thought to have a profound, yet undeterminable, influence on the relaxation times. Others⁴² have reported proton relaxation data for eight Argonne Premium coals and three oxidized coals and have shown that oxidized samples have shorter T_1^H values. Finally, in careful T_1^H and ESR studies of Argonne coals, various chemical treatments established that the important proton relaxation mechanism in lignite and subbituminous coals was due to the presence of paramagnetic mineral ions, whereas that in the higher rank coals is due to organic free radicals.⁴³

The problems were not confined to measurements of T_1^H . An early paper⁴⁴ reported proton $T_{1\rho}$ values for a pitch and three Canadian coals and had emphasized the effects of paramagnetic species, including oxygen, on the experimental results. Other studies indicated a general trend, but lack of any definitive correlation, between $T_{1\rho}^H$ values and radical concentrations for a series of 'more homogeneous' maceral concentrates.⁴⁵ It was concluded that the $T_{1\rho}^H$ values for macerals are clearly complicated by having two competing mechanisms for relaxation, i.e. molecular motion and heterogeneous spin diffusion to paramagnetic centers. Without knowledge of the relative contributions of each to the overall relaxation times in the individual samples, any meaningful interpretation of the data was impossible. In the case of a homogeneous resinite sample doped with increasing amounts of a stable organic radical, however, an excellent correlation of $T_{1\rho}^H$ with radical concentration could be established.

In contrast with proton relaxation, relatively little work has been done on the measurement of ^{13}C relaxation times in coals. Carbon-13 spin-lattice relaxation measurements have been carried out on a bituminous coal from the Powhatan No. 5 mine.^{46,47} It was established that aromatic resonances in this sample decayed with a single time constant, while the aliphatic resonances could be separated into two distinct regions having markedly different time constants for decay. Differences observed in the T_1^C values for different spectral regions were interpreted in terms of molecular motion, although the contribution of free radicals to spin relaxation were acknowledged as being important as well. Other researchers⁴⁸ investigated the effect of static field strength on the T_1^C relaxation parameters of five Argonne Premium coals and five Canadian coals, and correlated the relaxation times with various coal properties.

In a recent study,⁴⁹ eight Argonne Premium coals and three weathered Argonne coal samples were investigated and the proton and carbon spin-lattice relaxation times were reported for aromatic and aliphatic carbon atoms. In general, the proton and carbon spin-lattice relaxation data could be evaluated as the sum of two exponential decays. The longer components of carbon relaxation times in the laboratory and rotating reference frames were found to vary in a systematic way with coal rank, and the trends were explained in terms of motional properties of the coals and the presence of paramagnetic species. Marked increases in the carbon $T_{1\rho}$ values observed between pristine and weathered coals were interpreted to indicate a decrease in molecular mobility resulting from increased cross-linking as a result of oxidation.

2.1.4 Advanced Characterization Techniques

Several NMR methods have appeared in the recent literature on coal which deserve particular attention. They often

incorporate special pulse sequences for solids aimed at sensitivity enhancement, spectral simplification or resolution enhancement, and multidimensional NMR spectroscopy and imaging.

The first two-dimensional ^1H - ^{13}C COSY experiment on a coal was demonstrated in the mid-1980s.⁵⁰ By dispersing the carbon and proton spectral information over two dimensions (see Figure 6), the proton resonances became separated such that the aromatic, methylene and methyl protons could be resolved and their abundances estimated. Similar methods were applied to the analysis of the proton content of macerals.⁵¹ Overlapping carbon functional groups have been estimated from two-dimensional dipolar shift (DIPSHIFT) techniques.⁵² In the latter experiment, isotropic chemical shifts were plotted on a frequency axis facing dipolar shift sideband spectra on a second axis. Multiplicity of individual sideband patterns in the aliphatic region were then used to assign resonances in the isotropic spectrum on the basis of the number of protons attached to each carbon atom.

Dynamic nuclear polarization has been used with some success for the analysis of a wide range of coals of varying rank.⁵³ By polarizing carbon spins via the electron spins directly, or by CP techniques through the protons, large signal enhancements have been possible.⁵⁴ The technique has allowed the analysis of coals in short measuring times; however, because polarization is transferred from electron spins that reside predominantly within aromatic structures, the technique has generally overestimated the carbon aromaticity values in these systems.

Determination of the principal values of carbon CSA in anthracite coals and fusinite macerals through lineshape analysis has led to the quantitative analysis of the different carbon bonding types in these systems.⁵⁵ Using powder pattern lineshapes, three different bands due to aromatic condensed bridgehead and inner carbon atoms, and substituted carbon atoms were readily distinguished. The mole fractions of the condensed aromatic carbon atoms were then used to estimate the average cluster size of the polycondensed aromatic hydrocarbons in the coals. Later, VAS experiments were

Figure 6 (a) The heteronuclear shift correlation spectra of Illinois No. 6 coal with three fully resolved contours (1, 4, and 5) and two partially resolved contours (2 and 3) observed. (b) Proton spectra from slices at 1, 4, and 5

carried out in conjunction with powder pattern analysis in order to unscramble overlapping shielding tensors in coals and macerals.⁵⁶ A review of possible methods for obtaining carbon shielding tensor information on coals has recently appeared;⁵⁷ methods for separating individual CSA patterns in complex spectra include VAS, slow MAS, chemical shift correlation spectroscopy, magic angle hopping (MAH), stop-and-go (STAG) methods, DAS, and MAS with synchronized pulsing.

The first direct magnetic resonance imaging (MRI) experiment on solid coal and maceral specimens appeared in 1989.⁵⁸ These initial studies (see Figure 7) demonstrated the potential of MRI spatially to map proton distributions in whole coals. Individual macerals within the coals were readily distinguished by image contrast based on differences in proton density or spin–lattice relaxation. A subsequent MRI investigation focused on elucidating changes in the physical structure and on determining solvent accessibility parameters in solvent swollen coals.⁵⁹ Other researchers have utilized MRI to determine the distribution of water in coalified woods and low-rank coals.⁶⁰ Correlation of proton spin distributions determined by MRI with the void spaces from other techniques allowed analysis of porosity and permeability in the specimens. Transient MRI studies of solvent penetration into solid coal and polymer specimens has led to a detailed understanding of transport phenomena for systems in which the glass transition is induced by solvent; the data have led to the development of a new model for anomalous transport behavior in coals and other glassy polymer systems.⁶¹

2.2 Conversion Processes

The combined use of ^1H and ^{13}C NMR has been employed to examine the chemical behavior of coal, in reactions such as oxidation which may be undesirable, in thermolysis and pyrolysis reactions, and in upgrading reactions for its conversion into clean, high quality liquid fuels, and chemical feedstocks.⁶² Studies in the liquid state have provided information on the liquefied products, while solid state NMR

has been used to characterize the original coal material as well as the chars and cokes produced in these reactions.

Several researchers have focused their efforts on characterization of coal oxidation. Early proton relaxation time measurements have been used to explore oxidation of cokes in air at elevated temperatures. The data were compared with changes in the optical texture of the coke, and a correlation between the appearance of an isotropic phase and the T_1 minimum was found. T_2 experiments indicated that the mobile phase becomes more rigid, which was interpreted to reflect an increase in the degree of cross-linking. Structural studies carried out with ^{13}C CP MAS showed that a decrease in aromaticity accompanied oxidation of coals in air at elevated temperatures. Independent studies indicated that oxidation caused a loss of specific functional groups in the aliphatic region; an increase in carbon aromaticity was observed, contradicting previous results. Conflicting evidence was also reported in the literature concerning either the appearance or disappearance of certain aromatic structures, with specific reference to phenolic structures.

Other researchers have focused on elucidating structural changes after low-temperature oxidation, or weathering, of coals of different rank. Little change in the aromatic carbon content was noticed; however, the amount of the aliphatic CH_2 was found to decrease significantly after weathering. Dipolar dephasing studies were also in conflict with earlier elevated temperature experiments. Consequently, the entire body of evidence in the NMR literature has been inconclusive regarding specific structural changes that accompany oxidation. Investigations^{49,63} involving oxidation or prolonged weathering of Argonne Premium coals later established that changes in free radical content significantly affect pertinent relaxation times in CP MAS and dipolar dephasing experiments. These relaxation effects may in fact account for the discrepancies found in previous comparisons of NMR data between native and oxidized coal samples, ultimately leading to conflicting results on different coals.

The use of NMR for characterizing coal liquids derived from liquefaction processes began as early as 1975.⁶⁴ Proton NMR, and in several instances ^{13}C NMR methods, including CP and CP MAS, have been applied to study coal liquefaction under different conditions to produce solvent refined coals, H-coals and Synthoil products.^{10–12,65,66} NMR has played an important role in coal liquefaction research because it has been the only method able to characterize the complement of materials involved in the process, including the original coal feedstocks, liquid products, solid residues and products, catalyst materials, and solvent systems. The functional group analysis approach has been widely used to examine the structural changes in coal liquefaction and has led to the following general conclusions concerning the overall process in tetralin: (1) hydroaromatic structures are partially or completely dehydrogenated, while others are cleaved during the reactions; (2) alkyl groups in the products result from cleavage of the hydroaromatic ring structures; and (3) aromatic structures are formed via dehydrogenation reactions.

With the advent of ^{13}C CP MAS spectroscopy, not only liquid products but also the solid residues from liquefaction became amenable to analysis by NMR. The chars formed after prolonged reaction times at higher temperatures tended to have extremely high aromatic carbon content, (f_a up to 0.96). In general, it was found that the aliphatic content of

Figure 7 Two-dimensional xy images of resinite (left) and vitrinite (right) macerals using rotational gradients and MREV-8 back-projection reconstruction protocol with 90 projections about 180° , and 512 averages per projection. The recycle delays used in A–D were 235, 585, 1085, and 1585 ms, respectively

the chars decreased with increasing hydrogenation time while the composition of the liquid products remained relatively constant. Also observed was a marked decrease in the number of polar functional groups. The general conclusions drawn from the NMR results suggested a mechanism involving the decomposition of hydroaromatic structures, whereby under higher temperature reaction conditions an increasing proportion of aliphatic structures was converted into aromatic material and/or gaseous products. Furthermore, the increase in the polycyclic aromatic content meant that hydroaromatic systems were decomposing via retrogressive condensation reactions. Most recently, coal liquefaction residues were characterized by solid state CP MAS techniques.⁶⁷

Other researchers⁶² have focused on the use of CP MAS to study coking deposition on coal liquefaction catalysts, which was thought to be one of the principal causes of catalyst deactivation. Several studies⁶² have compared liquefaction behavior in the presence of different catalysts or with no catalyst at all, and have compiled results on the reaction yields and quality of liquid products. Both ¹³C and ¹H NMR have been used to monitor the hydrogen donor solvent employed in liquefaction. The results demonstrated that loss of hydrogen in the solvent occurs primarily via aromatization of hydroaromatic structures. By estimating the concentration of donatable hydrogen of the liquefaction solvent through chemical shift assignments, hydrogen donor values of various solvents were independently derived.

Labeling studies employing deuterated tetralin have been used with great success to study hydrogen transfer processes during liquefaction and to follow the incorporation of deuterium into liquid products.⁶² A combination of ¹H, ²H, and ¹³C NMR and separation methods such as gel permeation chromatography was employed to study the evolution of coal liquefaction products in *d*₄-tetralin.⁶⁸ Later on GASPE, INEPT, and two-dimensional *J*-resolved NMR were used to obtain more detailed structural information on exchange mechanisms of hydrogen and deuterium.^{11,69,70} The majority of studies on a wide variety of coals and catalyst systems led to a common conclusion: the distribution of deuterium in liquefaction products was found to be reasonably representative of the fate of hydrogen incorporation into coal tars. While there was some total scrambling of hydrogen, for the most part hydrogen was incorporated into aromatic residues and at α - and β -carbon atoms preferentially attached to aromatic structures.

The ability of NMR methods to provide reasonably quantitative information on the distribution of hydrogen in both the starting coals, liquid and solid reaction products, and solvents has made it possible to account for the total hydrogen consumption in liquefaction.⁶² A mass balance equation for the total consumption of hydrogen in liquefaction has been derived:

$$\Delta H = \Delta f_a + \Delta(C - C) + \Delta NOS \quad (3)$$

where ΔH is the net change in hydrogen between the original coal and all liquefaction products, Δf_a is the corresponding change in total aromaticity, $\Delta(C - C)$ is the total number of carbon-carbon bonds ruptured via hydrogenolysis, and ΔNOS is the composite loss of nitrogen, oxygen, and sulfur atoms. The NMR data combined with information from elemental analysis were used to estimate the fate of total hydrogen utilized in hydrogenation processes leading to reduction,

carbon-carbon bond-breaking reactions which generate either light gases or liquid products, and for removal of heteroatoms. The NMR approach of using the concept of total aromaticity as a means to assess the mass balance of consumed hydrogen has been an important step in evaluating the performance of liquefaction processes and has offered some of the best insights into coal liquefaction chemistry to date.

Numerous investigations have also been concerned with developing an understanding of the fundamental chemical processes involved during coal pyrolysis and carbonization.⁶² NMR has been used to study the response of coals to heating, by comparing data on solid and liquid products with the data obtained on the original solid coals. Researchers have developed comprehensive models based on the changes in functional groups during pyrolysis. Specific information on changes in aromaticity, degree of substitution on aromatic structures, types of aliphatic functional groups, and aromatic ring condensation have been compiled by both ¹³C NMR, and ¹H NMR using the approach of Brown and Ladner, together with compiled data on the yields of aromatic hydrogen and carbon as a function of temperature during pyrolysis. General conclusions have been summarized on the basis of the results: (1) only the weakest coal bonds fragmented at temperatures below 600 °C; (2) maximum yields were obtained at temperatures of 600–700 °C with little change observed in the aromatic structures and marked changes in the aliphatic components, suggesting that significant decomposition in the aliphatic substituents had occurred; and (3) at temperatures above 700 °C the less condensed aromatic structures began to decompose into gaseous products.

The nature of flash pyrolysis tars produced from a wide variety of coals throughout the world has been investigated by NMR techniques in several laboratories.⁶² In general, it was found that larger polycyclic aromatic ring structures were produced at higher pyrolysis temperatures. However, results compiled from a survey of many pyrolysis experiments suggest that the nature of the coal and the method of pyrolysis rather than the final pyrolysis temperature were most important in determining tar structure. Alkenes in the tars were correlated with the decomposition of polymethylene chains, while ¹³C NMR suggested that a large proportion of the alkyl carbon atoms were part of long-chain alkyl groups. NMR analysis of chars produced in variable temperature flash pyrolysis experiments showed that the aliphatic peak decreased with increasing pyrolysis temperature, while the aromatic band remained unchanged, suggesting that the aromatic content in the char was relatively constant. Furthermore, NMR studies demonstrated that the carbon aromaticity of the original coal, (f_a), or the amount of methylene structures present in the tars were linearly correlated with tar yields in coals ranging from bituminous to semianthracite; lignite tar yields, however, did not correlate well. Based on these results, it was concluded that aliphatic carbon atoms in coals, in particular the methylene groups, were essential to the production of pyrolysis tars. Later studies employing NMR considered correlating pyrolysis yields with the loss of specific regions of chemical shift within the aliphatic and aromatic resonance bands. The production of gases was consistent with decreases in the CH₂ resonance at 30 ppm. On the other hand, high tar yields correlated well with the loss of the remaining aliphatic groups in the region 13–47 ppm, i.e. consistent with the loss of hydroaromatic

structures in the coals. In addition, coal aromaticities correlated well with char production.

In general, the majority of coal processing technologies involve heating, and it is in this area that NMR has played a unique role in understanding the physical behavior of coal at the elevated temperatures typically employed in hydroliquefaction and other catalytic upgrading processes. Wideline ^1H NMR has been used to study changes in the molecular mobility or viscosity of coals during heating to temperatures as high as 875 K.^{62,71,72} Early studies measured changes in $\Delta H_{1/2}$. However, later on the use of second moment (M_2) analysis of the solid echo signal led to a more accurate representation of average molecular mobility. Variations in M_2 with temperature were consistent with a depolymerization of the coal structure followed by recondensation. The concurrence of temperatures for M_2 minima and bulk fluidity from Giesler plastometry suggested that there was a significant molecular basis to the thermoplasticity of coal. In general, a strong correlation was found between hydrogen content, and perhaps high sulfur content, with coal fusibility.

2.3 The Quest for Quantitation

^1H and ^{13}C NMR spectroscopy have been applied with great utility to the analysis of hydrogen and carbon functional group distributions in a wide variety of liquid and solid fuels and their reaction products. The increasingly important role over the past three decades of NMR as a characterization tool for fuels has led to a significant advance in our understanding of their structure, origin, and evolution. The enormous impact that NMR has made in the area of fuel research has been a direct consequence of its utility as a quantitative tool. In principle, NMR of spin- $\frac{1}{2}$ nuclei is unique as a spectroscopic method in that the transition probabilities of each and every isochromat in the absorption spectrum is the same, or unity. Notwithstanding this unique capability, from the outset concerns about the quantitative reliability of ^{13}C NMR spectroscopy has placed the general utility of the method in question. Carbon-13 NMR in liquids was perceived in this way until the mid-1970s, when its usefulness as an analytical technique was demonstrated by the judicious implementation of the proper pulse techniques and recycle delay times, sometimes with the aid of relaxation reagents to shorten spin-lattice relaxation times and to suppress the nuclear Overhauser effect. For ^{13}C analysis of solid coal samples, the issues regarding quantitation were not resolved until the late 1980s because of the enormous complexities involved.

With the advent of ^1H decoupling,¹⁵ CP¹⁵ and MAS,⁷³ which have made it possible to obtain high-resolution ^{13}C NMR spectra in solids in a relatively short measuring time, CP MAS techniques have been applied extensively in coal research.^{12,14,18,42,74-78} In fact, ^{13}C CP MAS NMR has become one of the most widely used methods for investigating coal. However, there has been growing concern during the past decade about the quantitative reliability of CP MAS spectroscopy for coal analyses. In the very first ^{13}C CP NMR study of coal,¹⁴ it was estimated that only about 50% of the total carbon spins could be detected via this technique. Since then the issue of quantitation in NMR analyses of coal and related materials has been a topic of much

debate.^{14,44,45,47,75,79-85} Although the quantity of observable carbon atoms for coals and their macerals have been shown to vary widely, the general consensus was that, for reasons which can be related to both specific coal properties and the applied NMR techniques, a substantial fraction of the carbon atoms was not observed.

It was known that coal is one of the most complex carbonaceous materials known. It was by nature an extremely heterogeneous solid composed of a number of distinct organic phases termed macerals, and to a lesser extent, of an inorganic mineral phase. Each maceral and mineral phase exhibited a unique set of physical and chemical properties that contributed to the overall behavior of coal. The macerals typically ranged in size from micrometers upwards, and pure bands were commonly found in coal seams up to meters in thickness. Consequently, maceral dimensions were sufficiently large to expect that nuclear spin diffusion across maceral boundaries would be incomplete on the NMR timescale, typically on the order of 1000–2000 pm and 10^4 to 2×10^4 pm in the limits of proton relaxation in the rotating frame and laboratory frame, respectively. This meant that nuclei within different maceral phases acted as isolated spin reservoirs with very different magnetic properties.

There were additional factors to consider as well. Individual macerals were in many instances intimately associated with inorganic minerals, some of which may contain paramagnetic ions. Moreover, the macerals contained different concentrations of organic free radicals, causing relaxation time differences that would ultimately govern the evolution of magnetization within these isolated domains. The presence of paramagnetic centers raised the possibility that significant portions of the carbons were sufficiently broadened or shifted outside the spectral range to render them invisible in the NMR experiment. Moreover, variations in free-radical content among these isolated phases was shown to lead to serious distortions in the carbon signal measured for the entire coal sample.

Thus, complexities in the organic, inorganic, and physical structures of coal limited the quantitative reliability of solid ^{13}C NMR measurements. The inherent limitations associated with measuring a complex solid such as coal were unavoidable. However, a fundamental understanding of these complexities was necessary in order to establish confidence limits for the measurements so that meaningful parameters could be obtained from the data.

A comprehensive review on the subject of quantitation in solid NMR analysis of coals has recently appeared.⁸⁶ In that review, several factors limiting quantitation in both single pulse and cross polarization experiments were discussed along with possible remedies. Important aspects to the problem of quantitation included in that discussion were: the nature of the unpaired electron spin interactions; interference between molecular motions and the proton decoupling field; insufficient MAS rotation; interference between molecular motions and MAS; consequences of long spin-lattice relaxation times; dependence of the Hartmann–Hahn matching condition; modulation of C–H coupling due to MAS; and complexities involving CP spin dynamics.

Finally, resolution of the issues concerning the quantitative reliability of solid ^{13}C measurements was made possible by the establishment of a standard, homogeneous suite of coal samples. As in other disciplines of fuel science, the complex nature of carbonaceous fuels together with the diversity of

samples chosen for study has made comparisons between published results difficult. With the inception of the Argonne Premium Coal Sample Program,⁸⁷ NMR results on a common suite of pristine coal samples spanning a diverse rank range could be compared.⁸⁸ Thus, valid comparisons between data measured using different experimental techniques and under a variety of different experimental conditions had become feasible for the first time.

A comparison has been made of data obtained from experiments which were carried out at static field strengths ranging from 1.4 to 9.4 T (corresponding to carbon resonant frequencies of 15–100 MHz) and using a variety of methods, including CP MAS, single pulse excitation (SPE) with MAS, MAS with TOSS, and DNP CP without MAS. Carbon aromaticities were determined from CP experiments employing contact times generally between 1–2 ms and, in certain instances, by mathematically fitting signal intensities derived from variable contact-time experiments. Proton decoupling field strengths employed were typically 40–82 kHz; MAS frequencies varied from 3 to 13 kHz. Recycle delay times ranged from 1–3 s in CP experiments to 60 s in SPE experiments.

For bituminous coals, mean carbon aromaticity values that were determined for three data sets (CP MAS, CP MAS at 2.3 T, and SPE) were found to be the same within the limits of the standard deviations. The results indicated that the variability in carbon aromaticities reported by different laboratories for the coals was greater than the differences observed between experimental techniques, i.e. CP and SPE experiments. However, the mean values from SPE experiments always tended to be on the high end of the range of CP values.

Differences in mean carbon aromaticity values for CP and SPE experiments were found to be significant for the two low-rank sub-bituminous and lignite coal samples. Their mean SPE carbon aromaticities were clearly higher by approximately 10% and 20%, respectively. The differences were accounted for by complications arising from paramagnetic transition metal ions intimately associated with the coal organic phase. The presence of paramagnetic metal ions in these coals was shown adversely to affect their spin–lattice relaxation properties,⁴⁸ and these factors were invoked to explain lower derived CP MAS aromaticity values resulting from reduced CP efficiencies.

Comparing mean CP and SPE aromaticity values for Argonne coals with aromaticities obtained by other pulse techniques showed the expected trends. While carbon aromaticities obtained using the TOSS pulse sequence in one laboratory were in reasonable agreement with the mean, those reported by other laboratories turned out to be significantly lower than mean CP or SPE aromaticity values. The disparity of the TOSS results illustrated the severe demands that are placed on proper implementation of the TOSS pulse sequence for quantitative analysis. On the other hand, aromaticity values obtained from DNP CP experiments tended to be high, which was entirely consistent with signal enhancement via electron–nuclear polarization from free radical centers that reside within aromatic coal structures.

The principal conclusion gleaned from the interlaboratory study was that SPE methods generally gave the most reliable results. Proper sample handling techniques to prevent oxidation or weathering of samples was also thought to be an important factor in the analysis of coals.

2.4 Origin of Coal and its Evolution

From the beginning of its deposition at the surface of the Earth and throughout its burial, sedimentary organic plant debris underwent progressive changes in composition and structure; when the process involved has related specifically to the metamorphosis of coal, it has been generally referred to as ‘coalification’.⁸⁹ The nature of metamorphic processes of coal has changed significantly at different stages of its evolution. At the earliest stages, coalification was dominated by microbial reactions and physical processes such as maceration and compaction. Later stages of coalification were governed predominantly by abiogenic chemical reactions such as dehydration, dehydrogenation, and aromatization, as well as polymerization and depolymerization reactions. The final stages involved graphitization processes, leading eventually to the formation of anthracite.

During the past three decades, there have been numerous investigations concerned with elucidating the important chemical processes responsible for the transformation of plant biopolymers into the specific organic macerals that compose coals.⁸⁹ During the 1980s, numerous studies employing NMR techniques sought to uncover the chemistry involved in the transformation of woody tissue, obtained from both natural and synthetic sources, into the maceral vitrinite. Often, NMR studies were carried out in parallel with analysis by mass spectrometry. The structural evolution of vitrinite was studied through detailed characterization of naturally occurring coalified log specimens which spanned the entire coalification range.^{90–94} In independent studies, laboratory simulated coalification experiments were carried out on lignin samples isolated from modern wood, in the presence of clay catalysts at relatively low temperatures (150 °C).⁹⁵ Subsequent simulated coalification investigations^{96,97} focused on solid state ¹³C and ¹H NMR analyses of synthetically prepared ¹³C-labeled lignins⁹⁸ and model compounds to monitor abiogenic evolution pathways. The remarkable parallels found between solid state ¹³C spectra of artificial coals and naturally occurring coalified specimens of similar maturation level laid the framework which revolutionized modern thinking on the process of coalification.

Previous views of coalification held that in early stages of diagenesis plant biopolymers (predominantly lignin) were degraded and depolymerized through microbial transformation into low molecular weight humic substances, and these materials subsequently repolymerized to form the macromolecular building blocks that became coals. The bulk of recent results from studies by NMR has not validated this paradigm of coalification. Rather, evidence has mounted indicating that coalification of woody tissue proceeded primarily by selective preservation of lignin structures, as biochemical processes removed carbohydrates preferentially, followed by a subtle thermal alteration of lignin directly into the macromolecules found in coal. There was little evidence to suggest that any major disruption in lignin structure had taken place; consequently, humic acids were no longer considered major intermediates in the formation of coal.

From investigations of coalification of both natural and synthesized precursors, evolutionary changes in the chemical structure of vitrinite were clearly delineated throughout the principal stages of coalification, and detailed mechanisms leading to its transformation could be sketched. It was shown that

initial biochemical stages of coalification involved the complete loss of hemicellulose structures, as well as a significant loss in cellulose from woody tissue, with minimal alteration of lignin. Later diagenetic stages leading to the formation of lignite coals resulted in complete loss of all the carbohydrates and some modification of lignin structure. The changes observed were predominantly rearrangement reactions of the aryl-ether bonds that formed linkages between the 3-methoxyphenol subunits; concomitant with these processes was demethylation of methoxyl groups followed by concerted methylation of the aromatic rings to produce methylcatechol structures. The final stages involving transformation into bituminous coals were characterized by reactions that resulted in complete demethylation of the aromatic methoxyl groups and subsequent reductive elimination of the 3-hydroxyl groups to form predominantly phenol-like building blocks. Progression to the higher rank bituminous coals was distinguished by the continued loss of oxygen functionalities along with ring condensation reactions leading to the formation of increased amounts of polycyclic aromatic structures.

3 APPLICATIONS TO SHALE OIL RESEARCH

Oil shales⁹⁹ are fine-grained sedimentary rocks that contain complex organic polymers ranging in molecular weight. There are two fractions of organic matter present: bitumen constitutes the fraction that is soluble in common organic solvents and kerogen constitutes the major portion of organic matter that is insoluble in organic solvents. The organic kerogen fraction is thought to be a cross-linked, three-dimensional macromolecular network of high molecular weight. Oil shale deposits were formed throughout geological time by the slow deposition of organic and inorganic residues in ancient lakes and inland seas. As the bodies of water stagnated and evaporated to dryness, the organic and inorganic matter compacted into sedimentary rock. The structure and composition of the inorganic and organic kerogen components of oil shale vary significantly with the location and the history of the sedimentary basin. If the organic portion originated from a land-based plant source, the kerogen fractions are similar in composition to coal, tend to be highly aromatic materials with hydrogen contents of about 5 wt%, and yield little oil on pyrolysis. On the other hand, kerogen fractions derived from marine aquatic sources tend to have high hydrogen contents ranging from 10 to 12 wt% and are good sources of oil.

Because oil shale kerogen was completely insoluble in common solvents, direct structural and compositional data were difficult to obtain without first performing time-consuming isolation and preparation procedures to produce kerogen concentrates that would be amenable to analysis. As was the case for coal, solid state NMR techniques fostered a resurgence of research devoted to characterization of oil shale in its native state. With the application of high-resolution proton CRAMP and carbon CP MAS spectroscopy, a great deal of fundamental information was obtained about the carbon and proton structure of these materials, about which there was little direct structural information known previously.

3.1 Structure Studies

The first application of NMR to the study of oil shales was reported in 1971, and this initial investigation was focused on the use of broadband ^1H NMR as a quantitative approach to predict oil yields that was less time consuming than Fischer assay methods.¹⁰⁰ Three years later, a more comprehensive study was reported in which pulsed ^1H NMR techniques were employed for oil shale characterization.¹⁰¹

Analyses of oil shale components by high-resolution ^1H and ^{13}C NMR have been carried out on samples from the Green River formation that were thermally fractionated into naphtha, light distillate, heavy distillate and residue fractions.¹⁰² Resonances in the spectra were assigned to normal alkanes, and to methyl- and dimethyl-branched alkanes, and the compositions of the various fractions were reported. Relaxation time experiments were correlated to the intermolecular segmental motion of the carbon chains in separate fractions. Solution NMR studies that followed have focused on applications of NMR to oil shale processing.^{103,104} Two-dimensional NMR techniques have been applied to the characterization of shale oils.¹⁰⁵ Carbon and hydrogen functional group distributions for oils, obtained from eastern and western oil shales within the USA, were determined using DEPT and quaternary-only (QUAT) pulse methods for editing carbon spectra.¹⁰⁶

The first solid state ^{13}C NMR spectra using CP enhancement techniques on native oil shales were reported in 1976,¹⁰⁷ however, the authors mentioned that the spectra were quite disappointing because of the lack of resolution between a broad aliphatic resonance band and a weak, partially resolved aromatic band. Later studies extended the CP measurements to include wide variety of oil shales.¹⁰⁸ Resing et al.¹⁰⁹ were the first to report CP MAS measurements on the aromaticity of a Colorado oil shale, the value of which was in basic agreement with that obtained by chemical degradation methods. In subsequent investigations, several laboratories performed CP MAS measurements in order to classify oil shale kerogens of varied origins and depositional environments throughout the globe.^{110–113}

Early studies were also concerned with interference from mineral matter, particularly carbonate minerals, with the signals arising from the organic carbon in shales.^{109,114} The general consensus reached was that spectra exhibited little interference from carbonates because of the long spin-lattice relaxation times of the minerals. For detailed investigations of the carbon structure of the organic fraction, NMR analyses were carried out on the kerogen concentrates that were prepared by removing the mineral matter by acid treatment (HCl or HF). Spectra of the kerogen concentrates were always found to be better resolved than those obtained from the raw shales, and even simple washing with HCl improved the quality of the spectra.^{111,115} The question remained, however, whether the preparation of concentrates by acid treatment had altered the chemical structure of the kerogen in the raw oil shale. A detailed study was carried out to address this issue, employing CP MAS techniques to characterize the organic carbon distributions in six oil shales and their isolated kerogen concentrates.¹¹⁶ It was determined that the raw shales and their corresponding kerogen concentrates had similar gross compositional features, e.g. carbon aromaticities, indicating that acid extraction did not significantly alter the chemical structure of the organic kerogen material. However,

Figure 8 CP MAS ^{13}C NMR spectra and f_a values of oil shale samples at various depths in the vicinity of a basaltic intrusion. Dark areas indicate regions of intrusion

carbohydrate structures if present in the original oil shales, were removed during acid extraction.

The utility of CP MAS NMR as a chemical elucidation method was demonstrated on a series of samples from a section of core taken from the Atlantic ocean, where a basaltic intrusion of magma had permeated the sediment during the Miocene period (see Figure 8).¹¹⁷ The thermal effects on the organic fraction were clearly visible in the spectra; samples closest to the basaltic intrusion zone clearly showed higher aromaticity values as a result of thermal cracking and subsequent loss of their long-chain aliphatic structures. Aromaticities derived from NMR were compared with results from more traditional vitrinite reflectance measurements, and it was concluded that NMR aromaticities were more sensitive and more quantitative to thermal changes in the kerogen structure.

NMR spectral editing using dipolar dephasing techniques has been applied to derive structural parameters for three oil shales from Colorado, Tennessee and Kentucky.¹¹⁸ Measurements were obtained on the native shales. Differences in carbon structure between the three shales were provided by the DD data, including the distribution of primary through quaternary aliphatic structures, protonated and nonprotonated aromatic groups, the number of methyl groups per aromatic

ring, the number of substituted or bridgehead carbon atoms per aromatic ring, and the minimum aliphatic chain length. A later investigation employed curve fitting procedures in conjunction with DD techniques to determine the distribution of carbon bonding types in a kerogen from the Green River Formation.¹¹⁹ Fourteen representative carbon functional groups were analyzed and these were used to derive an average structure for the kerogen. Analysis of the data indicated that the kerogen was composed of long-chain aliphatic residues as well as alicyclic ring structures, although relative proportions of each were not totally quantifiable on the basis of NMR results.

3.2 Resource Evaluation

The quality of the organic matter in oil shale has traditionally been used as the standard for its potential for bearing oil on heating. Conventional pulsed ^1H NMR has been employed as a rapid method of analysis for oil shale evaluation.^{108, 120–122} The method relies on the measurement of the amplitude of the free induction decay to assess the overall hydrogen content of the shale. In actuality, the measurement was simply a measure of the quantity of kerogen in the sample. To date, ^1H CRAMPS has not been employed for the analysis of oil shales.

With the development of ^{13}C CP MAS spectroscopy, a new method was introduced which has played a significant role in oil shale resource evaluation because it provides a direct means of analyzing aliphatic/aromatic carbon distributions in these systems, and thereby manifests an immediate relationship to yields of saturated oil products. Aliphatic structures tend to be hydrogen rich; thus oil shales having greater aliphatic carbon content were known to produce higher fractions of liquids than those more aromatic in nature.

The first CP MAS studies to establish a correlation between the aliphatic carbon content of oil shales and oil yields determined by traditional Fischer assay methods were performed by Maciel et al.^{123, 124} Several additional CP MAS studies followed on a wide range of kerogens and oil shales.^{125–128} The correlation between aliphatic carbon and oil yields was determined to be linear for samples spanning a diverse range of geological time periods, geographic locations and depositional environments. The excellent correlation between genetic potential, or the amount of oil and gas that an oil shale kerogen is able to generate, and fraction of aliphatic carbon has since been documented in several laboratories.^{129–133} Conversely, the aromatic carbon content has been shown to correlate with the carbon residue remaining after pyrolysis.^{115, 132–134} Solid state ^{13}C NMR has since been considered the paradigm for resource evaluation in the field, because the method relies on structure parameters that are closely identified with fuel yields. Moreover, the information is independent of the total kerogen content in the oil shale, which is often a misleading parameter for oil generation.

3.3 Oil Shale Conversion

Solid and liquid state NMR, in combination with elemental analysis and mass spectrometry, have provided valuable insight into the chemistry of oil shale conversion throughout the last two decades. From the perspective of processing, NMR has been attractive because it is capable of measuring directly

the changes associated with the carbon bonding distributions that occur as a function of temperature and other retorting parameters. Early studies involved liquid-state ^1H and ^{13}C NMR on oils produced from pyrolysis and hydropyrolysis of shales from eastern and western USA; a comprehensive set of average molecular structure parameters were derived for the hydrocarbon mixtures.¹³⁵ Research performed in several laboratories^{115,136–141} has combined CP MAS NMR measurements with data from elemental analysis to determine the degree of aromatization during oil shale pyrolysis.

Hershkowitz et al.¹³⁶ were the first to quantify the increase in aromatic carbon formed in pyrolysis of Colorado oil shale. Their experiments were carried out at a slow heating rate up to a temperature of 600 °C under high pressure (2600 kPa) N_2 or H_2 . The net increase in total aromatic carbon for the oil and residue products over that of the starting shale oil was determined by solution state and CP MAS ^{13}C NMR. The increase was rationalized in terms of aromatization of the aliphatic carbon functional groups and the associated evolution of light gases and oils that were composed of hydrogen-rich aliphatic species. Similar trends were observed in the pyrolysis studies of Green River and Kentucky oil shales,^{137,138} where increases in aromatic carbon content of 29% and 17% were reported, respectively. Consequently, it had been shown that aromatization of aliphatic structures in oil shales was indeed a facile thermal reaction, and that only by carefully controlling the pyrolysis temperature was it possible to minimize aromatization reactions responsible for oil loss.

4 OTHER FUELS

4.1 Petroleum

The earliest high-resolution ^1H NMR spectra of petroleum fractions, obtained at a frequency of 30 MHz, were reported in 1957.^{142–144} Two practical uses of the application of ^1H NMR in the petroleum industry appeared 2 years later, in 1959. A paper¹⁴⁵ was published which described NMR as a technique to evaluate the elemental hydrogen content of petroleum, and a patent¹⁴⁶ was issued in the same year concerning NMR as a method for process control for determining fuel quality on the basis of the degree of branching of alkylated aromatic hydrocarbons.

Although high-resolution ^1H NMR had proved to be valuable in the characterization of petroleum and petroleum fractions, the introduction of ^{13}C NMR in 1967 as a quantitative tool using time-averaged slow passage techniques¹⁴⁷ provided a prelude of what was soon to become a powerful analytical method. Nine years later, the first detailed ^{13}C NMR investigation of crude oils and petroleum fractions appeared using FT methods.¹⁴⁸ Replacement of continuous wave techniques by FT made the ^{13}C NMR characterization of crude oils and petroleum products more or less routine. Several conference proceedings and reviews have appeared in the literature which summarize much of the information that has been derived from NMR about the chemistry and structure of heavy crude oils and petroleum, including the use of NMR in petroleum exploration and as an oil logging tool.^{149–151}

Several fundamental advances have been realized in the elucidation of heavy oils by NMR. In 1981, Gillet et al.¹⁵²

presented and discussed numerous criteria necessary for obtaining quantitatively reliable structural parameters from NMR experiments. One year later, NMR was used to provide a 'fingerprint' of various crude oils.¹⁵³ SEBBORD pulse methods were used for spectral editing of carbon spectra of petroleum fractions, facilitating the discrimination of the different bonding schemes of aliphatic carbon structures, i.e. between CH , CH_2 , and CH_3 groups.^{154,155} The analysis provided sufficient information such that average structural parameters could be derived for these complex mixtures. Carbon chemical shifts and spin–lattice relaxation times were later used to characterize oil products.¹⁵⁶ Nitrogen compounds in crude oils have also been examined and identified with ^{13}C NMR.¹⁵⁷

The use of ^{33}S NMR as a tool for the characterization of petroleum oils¹⁵⁸ and an oxidized petroleum asphaltene¹⁵⁹ have been reported. The technique has met with limited success because of the considerable quadrupolar linewidths of sulfur combined with the large number of sulfur species present in these complex mixtures.

4.2 Peat

Humic substances have been described as the predominant fraction of the organic matter found in peat. Peat was formed in depositional environments where water had flowed near the surface of the peat profile, slowly but continually inundating the peat subsurface, and where anerobic conditions prevailed within the subsurface layers. These conditions led to the preservation, from oxidative and microbial processes, of the organic matter in peat which has always been thought to be derived from lignin from vascular plants.

An excellent treatise¹⁶⁰ on the use of ^{13}C CP MAS NMR as a structural tool for the investigation of sedimentary humic substances has appeared. The review covers the relevant literature concerning early liquid state and solid state NMR studies of aquatic and terrestrial sediments, and describes in detail recent CP MAS experiments on peat fractions from various geographical locations.

Early studies¹⁶¹ on humic acids and humins from holocene sediments were the first to suggest that CP MAS NMR can be used to distinguish between humic acids from terrestrial and aquatic environments on the basis of their carbon aromaticities. Source materials for the two sediments were entirely different: terrestrial sediments were based on lignin-derived material that was highly aromatic, whereas aquatic sediments were formed from primarily algal or microbial remains. In a subsequent paper,¹⁶² the same authors attributed the presence of aliphatic structures in marine humic acids to an algal source, and in terrestrial humic acids to lipid material. These initial observations provided the basis for understanding later NMR investigations on humic acids derived from peats.

In those subsequent studies,¹⁶⁰ CP MAS measurements were performed on isolated fractions of fulvic acid, humic acid, and humin from peats obtained from Minnesota, Okefenokee, and the Everglades. Absolute quantities of the aromatic and paraffinic structures, carboxyl, carbonyl and ether functional groups, and carbohydrates were determined and compared for individual fractions from the different peat samples. The data were used to determine the chemical composition of the varied structural components within peat samples from different

depositional environments, and the information was used to develop a model for the transformation of plant residues into humic substances. An investigation¹⁶³ published one year later focused on the use of ¹³C CP MAS spectroscopy, among other techniques, to identify structural changes that occur in humic acids during coalification through the stages of peat, lignite, and sub-bituminous coal.

4.3 Tar Sands

Tar sands are composed of complex mixtures of minerals containing aliphatic, heteroaromatic, and polycyclic aromatic compounds. Because of the strong intermolecular associations between molecules, organic matter in tar sands is often considerably viscous. Bitumen and heavy oil fractions of tar sands from different geographical locations differ widely in chemical composition and physical properties.

To date, there have been few published reports on the use of NMR for characterizing tar sands. Two early studies have attempted to characterize organic-inorganic interactions directly in heavy oil/bitumen-derived solids using ¹³C CP MAS NMR.^{164,165} A subsequent investigation¹⁶⁶ used ¹H CRAMPS to provide information on the types of hydrogen functionality that were present at the surface of tar sand residues. The data indicated that hydroaromatic structures were bound more strongly to the mineral surfaces, and that residues of tar sands after pyrolysis became highly aromatic in nature. Relaxation time (T_1) measurements¹⁶⁷ were used to determine the rates of intermolecular association of a tar sand bitumen after its thermally induced dissociation. Separate studies were carried out whereby viscosities of tar sand bitumens could be calculated from T_2 relaxation time measurements performed at room temperature.¹⁶⁸ Viscosities of bitumens from three US tar sands were correlated to weighted T_2 relaxation rates for semiliquid, mobile solid-like and rigid phases.

1 INTRODUCTION

The Earth and planets are complex systems which contain a wide range of chemical and physical environments. In and on the Earth, for instance, temperatures range from ca. -50°C at the polar regions to at least 4000 K in the core, and pressures range from zero at the surface to ca. 3.6 Mbar at the center. In detail the chemical environments of the Earth are extraordinarily diverse, but can be thought of as varying from near-surface hydrous conditions at relatively low temperatures and pressures (e.g., weathering and hydrothermal environments) to hydrous or anhydrous conditions at higher pressures and temperatures in the interior (e.g., partial melting conditions that produce magma in the mantle and lower crust and molten and solid metal outer and inner cores). The 90 natural elements are all of geochemical interest, although the bulk of the Earth is composed of about 10 elements, of which O and S are the most important anions and Si, Al, Fe, Mg, Ca, Na, Ti, K, C, and P are the most important cations. Most of the minerals in the crust and mantle (surface to a depth of ca. 2900 km) are silicates or aluminosilicates, and thus these materials (along with the economically important natural organic materials) are the focus of most NMR investigations relevant to geoscience.

NMR methods provide data and insight relevant to a wide range of geological problems that go far beyond simply characterizing the structures of minerals and natural organic and inorganic species. They have for instance, helped to obtain an understanding of the structure and dynamics of silicate and aluminosilicate glasses and melts (magma and lava), the structure and dynamics of water molecules and cations in clays and zeolites, reactions at mineral–water interfaces, the thermodynamics of homogeneous equilibrium in minerals, and the structural and dynamical changes which occur at phase transitions in minerals. Additionally, most products used by modern society start as natural materials, and NMR has

helped elucidate the mechanisms by which natural materials are converted to these products (e.g., clays to ceramics).

This article deals primarily with inorganic minerals and their reactions and briefly touches on natural organic materials and glasses. There are other chapters in this Encyclopedia concerning zeolites, amorphous materials, high-temperature NMR, and a variety of natural organic materials and products obtained from them that are relevant to geochemistry and geology.

2 HISTORICAL DEVELOPMENT

NMR investigations of minerals began soon after the discovery of NMR in 1945. The earliest study was the ^1H study of single crystal and powdered gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) by Pake¹ in 1948. This paper was an early example of how NMR methods can be applied to solids and paved the way to understanding the relationships between the structure and NMR behavior of water, and by implication other constituents of solids. Other early papers include work in the 1950s on ^{27}Al in Li-pyroxene (spodumene, $\text{LiAlSi}_2\text{O}_6$)² and ^1H in portlandite [$\text{Ca}(\text{OH})_2$].³

During the 1960s and 1970s most work on natural inorganic compounds used single crystal methods for ^{27}Al and alkali cations to investigate Al,Si order in the tetrahedral sites of aluminosilicates, to determine the relationships between the overall crystal symmetry and local site symmetry, to investigate structural phase transitions (SPTs), and to investigate the nature of the bonding in these materials.^{4,5} This work provided significant information complementary to the X-ray diffraction structural studies of these materials being undertaken at that time, but were limited by the need for ca. 1 cm^3 -sized single crystals. Investigation of the structure and dynamics of water molecules in minerals (especially clays) also grew rapidly during this time.^{6,7}

NMR applications to both organic and inorganic natural materials expanded rapidly beginning in about 1980, as the use of high-field superconducting magnets, the pulse Fourier transform method of data collection, and magic angle spinning (MAS) became common. To date there have been more than 1000 papers focusing specifically on geochemical and mineralogical problems and using these methods. The seminal papers were those of Lippmaa and his coworkers on the ^{29}Si MAS NMR of first silicates with a variety of structural types, and then zeolites.^{8,9} These were followed soon after by papers on ^{29}Si of the silica polymorphs and silicate and aluminosilicate minerals.^{10,11} The ability to examine quadrupolar nuclide via the $\frac{1}{2}$, $-\frac{1}{2}$ transition assumed great significance,^{12,13} because of the important natural nuclides only ^1H , ^{13}C , ^{29}Si , and ^{31}P have spin $I = \frac{1}{2}$. Work on natural organic compounds (e.g., coal and its precursors and derivatives, oil shale, and plants and their weathering products) also grew rapidly during this time.¹⁴

3 Al,Si ORDER IN ALUMINOSILICATE MINERALS AND CHEMICAL SHIFT CORRELATIONS

One of the most important applications of MAS NMR in the geosciences has been the investigation of Al,Si order

in aluminosilicate minerals. This work has used primarily ^{29}Si and to a lesser extent ^{27}Al , and has paralleled similar developments for synthetic zeolite catalysts and molecular sieves. This problem is of significance because silicates and aluminosilicates are the most abundant minerals in the Earth, and diffraction methods cannot effectively probe the state of local Al,Si order on tetrahedral sites if the Al and Si are not ordered onto crystallographically different sites.^{15,16} This local state of order can have a significant effect on the thermodynamic properties of the minerals, because of the relatively high energy of the tetrahedral Al–O–Al linkage and because of entropic effects. The concentration of tetrahedral Al–O–Al linkages is usually minimized (the ‘aluminum avoidance’ or ‘Loewenstein’s’ rule). This issue is of most significance for framework and sheet silicates (Q^4 and Q^3 polymerizations) and to a lesser extent for chain silicates (Q^2 polymerization), because Al does not often enter the tetrahedral sites of less polymerized structures.

The classic demonstration of the capabilities of NMR to investigate tetrahedral Al,Si order is the ^{29}Si investigation of the increase in Al,Si order in the framework structure of corderite ($\text{Mg}_2\text{Al}_4\text{Si}_5\text{O}_{10}$) with high-temperature annealing, and the relationship of the local state of order to the observed decrease from hexagonal through modulated to monoclinic symmetry.¹⁷ The results for corderite are clearer than for other aluminosilicates because the ^{29}Si peaks for Si on the two tetrahedral sites are better resolved. The most important results of this study are that corderite is always quite well-ordered (number of Al–O–Al linkages is always <1.5 per formula unit), that the number of Al–O–Al linkages decreases with increasing annealing time at temperatures between 1185 and 1400 °C, and that although the transition from modulated to monoclinic corderite is strongly first order as observed by X-ray diffraction (the average structure), the local Al,Si order as observed by NMR varies continuously and shows no discontinuity. Quantitative analysis of the NMR and thermochemical data indicate that the enthalpy of the ordering reaction $\text{Si–O–Si} + \text{Al–O–Al} = 2(\text{Si–O–Al})$ is about -34 kJ mol^{-1} , comparable to values determined for other aluminosilicate phases using similar methods.¹⁸

The ^{29}Si MAS NMR spectra of most framework aluminosilicates with more than one crystallographic tetrahedral site are not as well resolved as those of corderite because of overlap of the peaks from Si on different sites with different numbers of Al next-nearest neighbors (NNN), but in some cases analysis of the first and second moments of the spectra can provide useful information about the state of order.¹⁸

Analysis of the ^{29}Si MAS NMR spectra of sheet silicates (clays and micas) has also proven to be very fruitful, in large part because peak overlap is often not a problem due to the presence of only one tetrahedral site, over which Al and Si are distributed.¹⁹ Comparison of the observed NMR spectra and the results of Monte Carlo computer simulations of the Al,Si order in these materials shows that the short-range Al,Si order is greater than expected just by the absence of Al–O–Al linkages, and can be well described by the so-called homogeneous distribution of charge model. This model is based on the idea that the Al atoms distribute themselves in the way that most effectively balances the charges of the cations which occupy the interlayers between the aluminosilicate sheets. Site interaction energies for sheet silicates appear to be comparable to those of framework

silicates, and configurational entropies calculated via cluster variation methods based on these models are such that long range Al,Si order is not expected.¹⁹

^{27}Al NMR has wide application to minerals but has proven less useful in probing Al,Si order than ^{29}Si , because of the increased peak width due to unaveraged second-order quadrupole broadening under MAS. For oxide materials, octahedral ^{27}Al resonates near 0 ppm, whereas tetrahedral ^{27}Al resonates between 50 and 80 ppm. Thus, under MAS, peaks for these types of sites can normally be resolved, although quantitation of sites occupancies cannot always be assured. For tetrahedral Al, the chemical shifts generally become more positive with decreasing polymerization (paralleling the behavior of ^{29}Si).¹⁵ Unfortunately, in MAS spectra it is rare to be able to resolve peaks for Al on separate sites in Al,Si disordered phases, but in some cases analysis of the spinning sidebands of the satellite $\frac{1}{2}$, $\frac{3}{2}$ transitions can be useful.²⁰

One important feature of the NMR data for aluminosilicate materials is that there are several well-understood empirical relationships between ^{29}Si and ^{27}Al chemical shifts and structural and chemical parameters. These can be understood from quantum chemical principles, although computer capabilities still limit quantitative calculations.²¹ The most significant effects are due to nearest-neighbor (NN) coordination, with the chemical shift becoming more negative (more shielded) with increasing coordination. For ^{29}Si , the chemical shifts range from ca. -60 to -129 ppm for tetrahedral coordination and from ca. -180 to -210 ppm for octahedral coordination. Five-coordinate Si resonates near -150 ppm. For ^{27}Al the isotropic chemical shifts range from ca. $+55$ to $+85$ ppm for tetrahedral coordination, from ca. $+30$ to $+41$ ppm for five-coordination, and from near 0 to ca. 15 ppm for octahedral coordination.²²

The following are some of the most important correlations for tetrahedrally coordinated ^{29}Si (see also Kirkpatrick¹⁵ and Stebbins,²² and references therein).

1. For the SiO_2 phases, the ^{29}Si chemical shift becomes more negative with increasing mean Si–O–Si bond angle and mean Si–Si distance per tetrahedron, although the best functional forms are not well understood.²³
2. For silicates, the ^{29}Si and ^{27}Al chemical shifts become more positive with decreasing polymerization, although due to other structural effects there is considerable overlap of the chemical shift ranges.
3. For aluminosilicates with the same polymerization (e.g., Q^4), the ^{29}Si chemical shift becomes less negative as the number of tetrahedral Al next-nearest neighbors (NNN) increases, again with considerable overlap of the ranges.
4. For all aluminosilicates, the ^{29}Si chemical shift becomes more negative as the sum of the strengths of the NN and NNN bonds and the local group electronegativity increase.
5. For all aluminosilicates, the relationships with bond strength, NNN composition, interatomic distance, and interatomic angle can be accounted for by a single model involving these parameters.²⁴

There are also quite good empirical correlations between the ^{29}Si chemical shift of six-coordinate Si and various structural parameters. The best of these involves a parameter related to the bond strengths of the nearest neighbor cations and the angle of the Si–O–M bond.²⁵ Qualitatively, Si(6) chemical shifts become less shielded as the bond strengths of the nearest-neighbor cations decrease.

For tetrahedral ^{27}Al , the chemical shift correlations are less clear, but they generally become more positive with increasing Al/Si ratio, and framework (Q^4) structures generally yield less positive values than less polymerized phases.²² For both ^{29}Si and ^{27}Al , coordination to P causes less positive or more negative chemical shifts compared with similar sites coordinated to Si.

Aluminum-27 quadrupole coupling constants (QCCs) generally increase as the local site symmetry decreases,^{4,22} although there is no well-developed quantitative understanding of the relative effects of local symmetry and long range symmetry on their magnitudes.

4 ALKALI SITES IN ALUMINOSILICATE MINERALS

Many aluminosilicate phases, especially those with framework and sheet structures, compensate the charge imbalance caused by tetrahedral Al for Si substitution by the incorporation of alkali or alkaline earth cations in relatively large sites within the framework or between the sheets. In many cases the large cations are disordered because of a distribution of two or more species (e.g., Na and K) over one or more crystallographic sites, or because there are fewer cations per formula unit than available sites in the structure. In many cases the nearest-neighbor (NN) coordination of the large cation is poorly defined, with oxygens occurring at a range of interatomic distances. In some cases the cations are in rapid exchange among the various sites. In all of these cases, diffraction methods are insufficient to define adequately the distribution and behavior of the large cations, and NMR methods have proven useful. Most investigations of large cations in aluminosilicates have focused on the alkalis (primarily ^{23}Na), because the NMR-active alkaline earth nuclides have large quadrupole moments and thus typically yield broad peaks. NMR investigation of alkali cations began with single crystal work in the early 1960s²⁶ and greatly expanded after about 1982 with the advent of the pulse Fourier transform method and high-field superconducting magnets.¹⁵

An important example of the problem of defining the nature of the alkali site in framework aluminosilicates is the Na site of the feldspar albite ($\text{NaAlSi}_3\text{O}_8$). This site is quite distorted (its NN coordination could be considered to be any value from five to nine), and early structure refinements based on X-ray diffraction data used a so-called split site model in which the Na atoms are distributed over two positions in the same general site. Single crystal ^{23}Na NMR showed that this model is not correct and that in fact there is only one, well-defined but anisotropic, Na site.²⁶ Later MAS NMR work at higher field confirmed this result.²⁷ Sodium-23 MAS NMR of mixed Na,K feldspars shows that the Na site becomes larger and more symmetrical with increasing K/Na ratio, as demonstrated by progressively more negative isotropic chemical shifts and smaller QCCs. This observation demonstrates that the strain caused by K for Na substitution is quite long range (more than a unit cell) and affects not only the individual sites occupied by K but also those occupied by Na.²⁰ For Al,Si disordered phases, the singularities in the ^{23}Na peaks due to quadrupolar effects are usually poorly defined, probably due to a range of isotropic chemical shifts, quadrupole coupling constants, and asymmetry parameters caused by differences in the local Al,Si distribution.

Alkali cations in many framework aluminosilicates often have quite large diffusion coefficients at only moderate temperatures (a few hundred $^{\circ}\text{C}$), and it is likely that the motion of the alkali cations in them can be examined by high-temperature NMR. The Na behavior in the framework mineral nepheline (actual composition of the sample = $\text{Na}_{0.95}\text{K}_{0.05}\text{AlSiO}_4$) is an excellent example.²⁸ In this mineral Na is partitioned between two sites, which yield well-resolved ^{23}Na MAS NMR peaks. At ca. 300 $^{\circ}\text{C}$ these peaks begin to merge, and at 500 $^{\circ}\text{C}$ there is only a single peak. High-temperature X-ray structure refinements do not indicate the presence of structural distortions sufficient to cause the ^{23}Na signal for the two sites to become similar, and the best interpretation of these data is that above ca. 500 $^{\circ}\text{C}$ the Na is in exchange between these sites at frequencies greater than ca. 2 kHz. These frequencies are in good agreement with diffusion coefficients of about $10^{-12}\text{ cm}^2\text{ s}^{-1}$ for similar materials estimated from electrical conductivity.

Recent work shows that there are well-defined relationships between the ^{23}Na chemical shifts of aluminosilicates and their polymerization and NN Na coordination.²⁹ There has been less systematic study of the other alkali cations, and little systematic study of the alkaline earth cations, although ^{25}Mg , ^{87}Sr , and ^{137}Ba are observable for some materials.

5 STRUCTURAL PHASE TRANSITIONS IN MINERALS

Minerals, like all crystalline compounds, change their structure with changing environmental conditions (P, T, PH_2O , etc.). Many of these changes involve reconstruction of the crystal structure and occur via ordinary chemical reactions (e.g., solid state or solution–reprecipitation). Many minerals, however, undergo so-called structural phase transitions (SPTs) which involve adjustments of the structure but not destruction and formation of strong chemical bonds. Ferromagnetic and ferroelectric transitions are technologically important examples, and the α – β transition of quartz is the best known mineralogical example. SPTs can have significant effects on the thermodynamic and mechanical properties of materials in which they occur and thus can be of considerable geological importance.^{30,31}

The first geologically important SPT to be investigated by NMR was the P–I transition in the Ca-feldspar anorthite ($\text{CaAl}_2\text{Si}_2\text{O}_8$). This phase is the end-member of the Ca–Na plagioclase feldspar series, which is the most abundant mineral in the Earth's crust. In the 1960s and 1970s there had been considerable controversy about the existence of this transition, and single crystal ^{27}Al NMR results demonstrated that the number of Al sites in anorthite is reduced from eight to four with increasing temperature at ca. 240 $^{\circ}\text{C}$.⁵ Recent ^{29}Si MAS NMR work confirms this result and demonstrates that the number of Si sites is likewise reduced from eight to four at the transition.³¹

The SPTs of the SiO_2 polymorphs, quartz, cristobalite, and tridymite, and their AlPO_4 analogs have been the focus of extensive recent NMR investigation.^{32–34} These SiO_2 phases are important both naturally and technologically, and their AlPO_4 analogs, which have similar SPTs, allow investigation of the structural changes through the quadrupole interaction

of ^{27}Al , as well as through the chemical shifts and ^{17}O quadrupolar interaction. Data for these phases are also an essential base from which to investigate the SPTs of the wide range of minerals and synthetic compounds with stuffed quartz, cristobalite, and tridymite structures (e.g., nepheline, eucryptite).

For the SPTs of these materials, the chemical shifts, relaxation rates, and ^{17}O and ^{27}Al QCCs provide clear probes of the temperatures, extent, and hysteresis of the transitions, and also provide information about the local structural changes which occur. For instance for SiO_2 -cristobalite, changes in the ^{29}Si MAS NMR spectra clearly reflect the changes in the mean Si–O–Si bond angle per tetrahedron with temperature in the low-temperature phase and the discontinuous change in this parameter at the SPT. The T_1 relaxation rates also change discontinuously.^{32,33} X-ray diffraction indicates that the low-temperature phase is tetragonal and that the average structure of the high-temperature phase is cubic. ^{27}Al NMR results also indicate that the Al site of the high-temperature AlPO_4 cristobalite phase has cubic symmetry on timescales longer than about $1\ \mu\text{s}$.³³ The SPT is associated with the onset of diffuse streaking in electron diffraction patterns, indicating disorder in the high-temperature phase. However, the mean Si–O–Si bond angle in the high-temperature phase determined from empirical correlations is about $152.5 \pm 1^\circ$, inconsistent with the value of 180° required by cubic symmetry. The only explanation consistent with all these observations is that the oxygen atoms in the high-temperature phase are dynamically disordered on positions located on an annulus around the mean oxygen position, and that the average structure as observed by X-ray diffraction is a dynamical average of structures that instantaneously are not cubic. The high-temperature phases of tridymite appear to behave in a similar way,³⁴ and similar dynamical disordering is likely to occur in many materials with relatively open structures. NMR will be an important tool in investigating such materials.

6 HIGH-PRESSURE MINERALS

The structures of silicate and aluminosilicate materials normally change less with increasing pressure than, for example, organic compounds or alkali halides. Nonetheless, the pressures in planetary interiors are extremely large, and the minerals present are denser and have different structures than those present at and near the surfaces. One of the most dramatic changes in the Earth's structure occurs in the depth range 400 to 650 km ($P = \text{ca. } 130 \text{ to } 220 \text{ kbar}$). In this region, the so-called transition zone of the mantle, the densities and sound velocities as observed by geophysical techniques increase dramatically (ca. 15–20%). High-pressure and -temperature laboratory experiments indicate that the structures of the major minerals of the upper mantle (olivine, pyroxenes, and garnets) transform to denser phases in this pressure range. Thus, although there is considerable controversy about whether there is a change in the bulk composition of the Earth at this depth, there is no controversy about the fact that structural changes in the minerals present contribute significantly to the observed changes in properties.

The most significant aspect of the structures of these high-pressure minerals is that they contain octahedrally coordinated Si [Si(6)], as opposed to the tetrahedrally coordinated

Si [Si(4)] of lower pressure phases. NMR of quenched samples has played a useful role in understanding the structures of these high-pressure phases.²⁵ Unfortunately, in situ high-pressure/high-temperature NMR probes with sufficient sensitivity and resolution to probe oxide materials usefully do not appear to be on the horizon.

An example of the ability of NMR to address structural questions concerning high-pressure phases is a recent study of Mg₂Si disorder on the six-coordinate sites of MgSiO_3 -garnet.³⁵ At low pressures this composition has a pyroxene (chain silicate) structure in which all the Si is four-coordinate and connected in single chains (Q^2 polymerization). Between ca. 170 and 220 kbar, depending on the temperature, it has a garnet structure consisting of isolated Si tetrahedra (Q^0 polymerization) connected by octahedra occupied by Mg and Si. At pressures above about 220 kbar, it has a well-ordered perovskite structure with all the Si in six-coordination. The garnet phase has two crystallographically distinct octahedral sites and three crystallographically distinct tetrahedral sites. All of the tetrahedral sites are fully occupied by Si, and X-ray diffraction indicates that one of the octahedral sites is occupied primarily but not completely by Si and the other primarily but not completely by Mg. ^{29}Si MAS NMR spectra readily resolve not only Si(4) and Si(6), but multiple Si(4) sites.³⁵ Calculations based on simulations of this spectrum indicate that in fact one of the octahedral sites is 0.88 Mg and 0.12 Si, and the other is 0.88 Si and 0.12 Mg. Similar garnet samples with some Al for (Mg + Si) substitution have cubic structures with only one octahedral site. For these samples, ^{27}Al and ^{29}Si NMR shows that all of the Al and Mg and part of the Si enters the octahedra site, that the remainder of the Si fills the tetrahedral sites, and that the Al, Mg, and Si on the octahedral sites are essentially randomly distributed.^{35,36} High-pressure minerals are difficult to synthesize because large and complex pressure vessels are needed to generate the simultaneous high pressures and temperatures (ca. 1000–2000 °C). Most samples are quite small (a few mg), and the best results are obtained with ^{29}Si -enriched material.

Future NMR work on high-pressure phases is likely to focus considerably on ^1H and ^2H , because hydrogen (primarily as OH groups and water molecules) plays an important role in controlling the physical properties of the upper mantle and in the formation of magma and lava. It appears that hydrous aluminosilicate minerals are the dominant reservoir of H in the mantle, but the structures and physical and chemical behavior of these phases are poorly known.

High pressures are also generated at meteor impacts, and NMR has also proven useful for characterizing the materials resulting from both natural meteor impacts and laboratory experiments simulating impact conditions. It is possible, for instance, to determine readily the presence of high-pressure SiO_2 phases such as coesite and stishovite, to characterize the amorphous phases sometimes created during shocking.³⁷

7 EXCHANGEABLE WATER AND CATIONS IN CLAY MINERALS

Clay minerals are stable and nearly ubiquitous at low pressures at or near the Earth's surface, at the opposite end of the spectrum of physical conditions from the dense

aluminosilicates just described. There is a bewildering variety of clay minerals, but most have structures containing parallel sheets of octahedral and tetrahedral sites, with the tetrahedral sites having Q^3 polymerization. Cation substitution in both types of sites [e.g., Al(4) for Si(4), Mg(6) for Al(6), and Li(6) for Mg(6)] is common and causes a net negative charge on the aluminosilicate sheets, leading to the incorporation of mono- and divalent cations and water molecules between the sheets in the so-called interlayer. Organic cations and neutral molecules are also readily incorporated into clay interlayers.

The behavior of the cations and water in and on clays is critical in many important geochemical and biological processes, including such diverse phenomena as plant growth, adsorption and release of agricultural fertilizers, the stabilization of road beds, the movement of organic and inorganic pollutants and radionuclides in the environment, and the migration of petroleum in the subsurface. Because single crystal X-ray diffraction is not possible for most clays due to their small grain sizes, NMR spectroscopy has played a key role in understanding the structural environments and dynamical behavior of cations and molecules in clay interlayers.

In addition, because clay minerals have such large surface areas, they have proven to be excellent materials with which to study the fundamental behavior of water near surfaces. NMR investigation of water, inorganic cations, and organic molecules on clays began in the late 1960s and has continued to the present.

A clay grain presents primarily planes of protonated or nonprotonated oxygen atoms to water molecules, ions, or other species with which it is in contact. The presence of this surface changes the structural arrangements and dynamical behavior of these molecules and ions within about three molecular layers of the surface. These effects can be observed as changes in NMR relaxation rate, chemical shift, and quadrupole coupling.^{7,38}

Most NMR investigations of mineral surfaces up to the 1980s focused on the structural environments and dynamical behavior of water and used ^1H and ^2H as the primary probes. Two types of samples have been investigated. One type (low hydrated) has a relatively low water content, with most of the water contained in the interlayers of collapsed clays. In this case the bulk of the signal comes from species near or at the surface. The other type of sample has a large water/solid ratio (high hydrated), and the bulk of the signal comes from molecules not near the surface. In this case, the surface and bulk species are in rapid exchange, and the effects of the surface are observed as changes in, for example, the ^2H quadrupole coupling with changing water/solid ratio.

High hydrated systems yield quadrupole doublets for $^2\text{H}_2\text{O}$ and Pake doublets for $^1\text{H}_2\text{O}$.^{6,39,40} The splittings normalized for surface area are remarkably similar for all clays examined, suggesting that the presence of the surface but not the composition of the clay dominates the reduction of the reorientation rate and the increase of the anisotropy of the reorientation due to the surface. Theoretical work supports this idea.⁴¹ ^2H T_1 relaxation rates for such systems indicate that reorientational correlation times are of the order of 10^{-10} s near the surface, compared with 10^{-12} s in bulk $^2\text{H}_2\text{O}$, with only a small pressure effect up to 5 kbar.⁴² The peak splittings and relaxation rates clearly show that the effects of the surface on the electric field gradient and rates of reorientational motion extend to only approximately three molecular layers from the surface.

Additional ^2H and ^{17}O results suggest that the charge of the counterion significantly affects the axis of rotation of water molecules at the surface.⁴⁰ If the counterion is Na, the water molecules bond relatively weakly to it and relatively more strongly to the oxygens of the surface via hydrogen bonds. In this case the molecule rotates predominantly around the hydrogen bond. If the counterion is Ca, however, the M–O bond is stronger, the hydrogen bond to the surface is relatively weaker (although absolutely stronger), and the axis of rotation is the metal–oxygen bond. This change is consistent with increased polarization of the water molecule in the presence of a higher charge cation and with the observed increased Brønsted acidity under these conditions.

Low hydrated clay/water systems can be investigated in more detail, in large part because it is possible to undertake experiments with partially oriented samples in addition to those with random particle orientations. Partially oriented samples are made by sedimenting clay flakes from water such that their C^* axes are subparallel. Directions perpendicular to C^* are not oriented. The C^* axis is perpendicular to the aluminosilicate layers. Clay particles typically have diameters of ca. $1\text{--}2\ \mu\text{m}$ and thicknesses of a few tens of Å.

The most well-understood low hydrated system is the two-layer hydrate of Na-exchanged vermiculite.⁴³ Vermiculite has a relatively large negative charge on the aluminosilicate structure due to Al for Si substitution in the tetrahedral sites, and thus accepts relatively large concentrations of exchangeable interlayer cations and their associated shells of hydration water. The interlayer structure of vermiculite is much more ordered than those of most other clays, because of the proximity of the negative charge deficit to the interlayer. Most montmorillonites, on the other hand, have quite disordered interlayers because they develop their negative charges by substitution in the octahedral layers and their net layer charges are smaller than those of vermiculites. In the Na two-layer hydrate of vermiculite, each Na has six water molecules in its hydration shell. Analysis of ^2H and ^1H NMR lineshapes and T_1 relaxation data for oriented aggregates of this material leads to the following conclusions:

1. The threefold (C_3) axis of the $\text{Na}\cdot 6\text{H}_2\text{O}$ cluster is parallel to the C^* axis, and the entire hydration shell rotates around the C_3 axis at frequencies greater than ca. 23 kHz.
2. Each water molecule is rotating at frequencies of about $10^{10}\ \text{s}^{-1}$ around the Na–O vector. This vector is perpendicular to the H–H vector of the molecule and at an angle of about 65° to the C^* axis.
3. Proton exchange appears to be occurring between the molecules of the cluster at frequencies of $10^4\text{--}10^5\ \text{Hz}$, 10–100-times faster than in bulk water.

The presence of a cation near the surface appears to be necessary to cause the preferential orientations of the water molecules observed for most clay interlayers.⁴⁴ ^1H and ^2H lineshape, T_2 , and T_1 results for water on halloysite show no preferred orientation of the molecules but do show an anisotropy of the molecular motion, with the rate of rotation around the C_2 axis of the water molecule being more than two orders of magnitude greater than the rate of rotation perpendicular to this axis. Unlike most other clay minerals, halloysite has no net charge on its aluminosilicate layers and thus no essential exchangeable cations.

Other low hydrated systems in which the behavior of the water molecules has been investigated include one-layer

hydrates of vermiculite with various exchanged cations, and various montmorillonites.⁷ For the one-layer hydrate of Li-exchanged hectorite, the Li is apparently coordinated by only three water molecules, with the remainder of their coordination shells made up of basal oxygens of the aluminosilicate layers.

The advent of high-field spectrometers has made it possible to use NMR methods to investigate not just the structure and dynamical behavior of water molecules in clays, but also the same properties of the interlayer cations. To date, interlayer ⁷Li, ²³Na, ³⁹K, ¹³³Cs, and ¹¹¹Cd have been observed (see Klopogge et al.,⁴⁵ and references therein).

For instance, the behavior of ¹³³Cs in the clay interlayer shows extremely complex behavior depending on temperature, concentration, and partial pressure of water.⁴⁶ Under water-saturated conditions (the typical state below the water table), the room-temperature ¹³³Cs MAS NMR spectrum of Cs-exchanged hectorite (an Li-smectite) consists of two narrow peaks. One of these is for Cs in the aqueous phase and the other is for Cs in the clay interlayer. With decreasing temperature the peak for Cs in the interlayer splits into two, and below ca. -60°C there are two well-resolved peaks. Simulation of the spectra show that the room-temperature (RT) peak for interlayer Cs is due to dynamical averaging of the signal from Cs on the two sites represented by the two low-temperature peaks at frequencies greater than ca. 10 kHz. One of the observed sites is probably Cs in inner-sphere complexes relatively tightly bound to the basal oxygens of the silica tetrahedra, and the other is probably Cs in outer sphere complexes not tightly bound to the basal oxygens. Similar behavior is observed at 100% RH with no bulk liquid phase present. Under fully dehydrated conditions, however, the Cs chemical shifts are very different, and RT site exchange does not occur. There are two interlayer Cs sites with greatly different NN coordinations, possibly nine and 12.

Hectorite develops its layer charge in the octahedral sites, which are separated from the interlayer by a layer of Si tetrahedra. The interlayer Cs is, thus, bound relatively weakly to the silicate structure and can move relatively easily. This contrasts with the behavior of Cs in vermiculite, which develops its layer charge by Al for Si substitution in the tetrahedral sites. In vermiculite there appears to be no detectable motion of the Cs and the chemical shift does not change with changing hydration state.^{46,47} The difference is probably due to relatively tight bonding of the Cs to the basal oxygens of the tetrahedral sheets.

For vermiculite the ²³Na and ¹¹¹Cd NMR spectra are quite well resolved and are generally in agreement with the results concerning the behavior of water molecules in vermiculite interlayers described above.⁴⁷ For ²³Na and ¹¹¹Cd, the two-layer hydrates, one-layer hydrates, and dehydrated phases (which are produced at different relative humidities) yield different chemical shifts for the exchangeable cations, with the shielding increasing with progressive dehydration (more negative chemical shifts).

Potassium-39 is difficult to observe in solids due to its large quadrupole moment and low resonance frequency, but spin echo pulse sequences and high fields yield useful static spectra of powder and oriented aggregates of clay minerals.⁴⁸ For montmorillonite, signals for K in collapsed and uncollapsed interlayers can be resolved, providing evidence for increased interlayer collapse with an increasing number of wetting and drying cycles.

Many organic cations and neutral molecules can be readily incorporated into clay interlayers, and their structural environments and dynamical behavior can be observed by ¹H, ²H, and ¹³C NMR. Nuclides of other elements that are often part of organic molecules (e.g., ¹⁴N, ¹⁵N, ³¹P) could also be observed. There have been few studies of the structure and dynamics of organic molecules and cations in clay interlayers, but the available results suggest that such work has considerable promise. For benzene in the interlayers of an oriented sample of hectorite, ¹³C NMR shows that at room temperature the benzene molecules have their hexad axes approximately parallel to the planes of the clay layers and that the molecules are in rapid rotation about the hexad axis.⁴⁹

It is likely that there will be considerable future efforts to use NMR methods to understand clay interlayer behavior because of the significance of adsorption on clays to environmental concerns. The discussion in this section has focused on NMR investigation of water molecules and interlayer cations, but as noted above ²⁷Al and ²⁹Si are useful probes of the aluminosilicate portion of clays.^{19,50,51}

8 THERMAL DECOMPOSITION OF PHYLLOSILICATE MINERALS

The decomposition of phyllosilicates and other fine-grained hydrous aluminosilicates by heating is a common route for producing ceramic materials such as catalyst supports and mullite. ²⁹Si and ²⁷Al NMR provide useful insight into the mechanisms by which such reactions take place.^{52,53} Decomposition of the 1:1 phyllosilicate kaolinite [Al₂Si₂O₅(OH)₄] is the best studied, and proceeds from crystalline kaolinite through a poorly crystalline compound called metakaolinite at ca. 500–550°C to a mixture of γ-alumina, mullite (often poorly crystalline), and amorphous silica at ca. 1000°C.^{53–56} NMR has been instrumental in demonstrating that the actual reactions are much more complicated than previously thought based on XRD data. In particular, metakaolinite appears to be a complex mixture of ill-defined regions with three-dimensional silica-rich volumes in which Q⁴ units dominate, aluminosilicate regions, residual kaolinite-like regions, and alumina-rich regions with little silica. Five-coordinate Al appears to be an important species, although its structural role is not fully understood.

9 NMR OF LESS ABUNDANT ELEMENTS: ³¹P, ¹¹B

Although most natural inorganic compounds in the Earth are aluminosilicates, there are also a great many other kinds of compounds. Borate and phosphate minerals are common and have been investigated by NMR, especially via ¹¹B and ³¹P. Results for these phases are described below. Carbonates are also common, but their range of ¹³C chemical shifts is small.⁵⁷ Ferric oxides and oxyhydroxides and sulfides of many types are very common, but have not been usefully investigated by NMR. NMR investigation of many other elements, perhaps most notably the alkaline earths, is limited by technical limitations due primarily to low frequencies, large quadrupole moments, long relaxation times, or large chemical

shift anisotropies. Other elements are normally limited by very low concentrations in most minerals (e.g., the rare earths).

Borate minerals are most abundant in unusual near-surface geochemical environments in which B is concentrated by aqueous transport and precipitation. Otherwise, B occurs in borosilicate minerals or at trace levels in many minerals. Both wide-line and pulse Fourier transform MAS ^{11}B NMR can distinguish tetrahedrally coordinated B [B(4)], asymmetrical trigonal B [B(3)], and symmetrical trigonal B.^{58,59} The ^{11}B chemical shift is also useful for distinguishing B(4) sites linked to other B(3) or B(4) sites (values near 0 ppm) from those linked to Si tetrahedra in a borosilicate environment (values near -2 ppm).⁵⁹

Phosphate minerals occur in many geochemical environments, and almost all are orthophosphates. There is a relatively large ^{31}P chemical shift range of ca. 30 ppm due to different nearest-neighbor linkages.^{60,61} Alkali and alkaline earth phosphates commonly have chemical shifts that are positive or near 0 ppm, whereas aluminophosphates typically have more negative chemical shifts. The AlPO_4 analogs of the SiO_2 phases quartz, cristobalite, and tridymite have ^{31}P chemical shifts between -25 and -30 ppm. Synthetic compounds have an even larger range. The results for phosphate minerals with known structures have provided references with which to interpret data for phosphate, aluminophosphate, and phosphosilicate glasses, and for understanding the structural environments of phosphate adsorbed on mineral surfaces.⁶²

10 ^{17}O NMR OF MINERALS

Oxygen is the most abundant anion in the Earth and is thus a major component of most minerals. The only NMR-active oxygen nuclide is ^{17}O , which has a natural abundance of only 0.37% and, thus, for solids can only be observed in synthetically-enriched samples. For the most part, NMR work on ^{17}O in minerals and mineral analogs has been limited to the investigation of materials with known structures.^{63,64} The database for model compounds is now large enough that recent studies have used it effectively as a probe of less well-understood materials and structural phase transitions.³²

For oxide materials, the ^{17}O chemical shifts are mostly positive relative to water and range from nearly +1200 ppm for Ag_2O to -227 ppm for Cu_2O . For silicates and aluminosilicates, most chemical shifts fall in the range +170 to near 0 ppm, with the values for nonbridging oxygen sites having a wider range than bridging oxygen sites.²² Oxygen-17 quadrupole coupling constants for simple oxides are typically quite small (<ca. 2.5 MHz, and often less than 1 MHz), due to the high symmetry of most of these materials. For silicates and aluminosilicates, the QCCs are typically >2.5 MHz, with bridging oxygen sites typically having values >4.0 MHz. Oxygens in OH linkages appear typically to have the largest values (>6.0 MHz). Most silicates and aluminosilicates have orthorhombic, monoclinic, or triclinic symmetry, and thus significant electric field gradients at their O sites.

The use of dynamic angle spinning (DAS) to investigate ^{17}O in solids is a recent and potentially very productive approach. Under MAS conditions there is often extensive peak overlap due to unaveraged second-order quadrupole interactions which limits spectral resolution. DAS resolves, for example, signals

for the nine O sites in wollastonite (CaSiO_3) with only some peak overlap.⁶⁴

High-temperature ^{17}O NMR has also been useful in investigating the dynamics of silicate melts.⁶⁵ In particular, these results demonstrate conversion between bridging and nonbridging oxygen sites and provide support for a model of viscous flow of these materials involving the formation and destruction of five-coordinated Si sites. Silicon-29 NMR has demonstrated the presence of such sites in some glasses.⁶⁶

11 NATURAL ORGANIC MATERIALS

Naturally occurring organic compounds are not abundant in the Earth overall, but are common near the surface and are essential for the existence of life on this planet and for crop production and most energy used by humans. There is an extensive literature concerning NMR investigation of natural organic compounds of many kinds [plants, the weathering products of plants (humic and fulvic acids), peat and coal, oil shale, and petroleum]. Much of this literature is reviewed in the articles in this Encyclopedia on fossil fuels, cokes, rock porosity and petroleum flow, and wood. Articles by Wilson¹⁴ and Hayes et al.⁶⁷ provide introductions to applications of NMR for understanding the structures of these materials.

12 NATURAL GLASSES AND MELTS

Natural glasses are formed most commonly by quenching natural aluminosilicate melts (magma below ground and lava above). Thus their structures and properties are quite similar to those of synthetic glasses. Motivations for studying the structures of natural glasses include understanding the crystallization and fluid flow properties of natural melts,^{65,68} understanding the effects of water and CO_2 on these properties, and understanding the hydration and dissolution behavior of natural and synthetic glasses (including nuclear waste glasses).⁶⁹⁻⁷³ There is extensive overlap of the literature concerning natural and synthetic glasses, and these results are discussed in the articles on *Amorphous Materials* and *Quadrupolar Nuclei in Glasses* in this Encyclopedia and in recent reviews.^{65,74}

1 INTRODUCTION

The production of hydrocarbons involves, inter alia, drilling wells into oil-bearing rock strata at selected locations and utilizing a number of production strategies, often referred to as primary, secondary, etc., where primary, for example, refers to the fluid production consequent on the release of the naturally occurring internal pressures of the reservoir, with secondary implying some form of pressurization of the reservoir through the injection of water, gas, or some similar combination. Wells are expensive and the choice of where to place them for optimum production relies on assessments based on a wide range of information. Part of this assessment utilizes samples of rock, referred to as 'cores' taken at various depths whilst drilling wells, usually at the appraisal stage of determining a reservoir's potential. This article is concerned with the use of NMR imaging to investigate and characterize the properties of such core samples. These have traditionally been subjected to laboratory measurements of the basic properties of porosity, ϕ , and permeabilities, κ , the first being the fraction of the rock volume available to contain the reservoir fluids, comprising one or more of gas and liquid hydrocarbon and aqueous phases, and the second a measure of the ability of these fluids to flow through the rock under given fluid composition, pressure gradient and temperature conditions. NMR and NMR imaging have the potential both to support the evaluation of production strategies in a given reservoir and to advance the understanding of the underlying fluid dynamic processes. In neither case has NMR yet made the impact it could. An important issue is the nature of the samples studied and the degree to which they are representative of the conditions in the reservoir. This is a more subtle issue than just a matter of temperature and pressure. On retrieving core material it may be recovered in a 'preserved' state where attempts are made to retain the fluid saturations which existed in the reservoir. Releasing the pressure and lowering the temperature will alter these and can also affect the surface characteristics or wettability of the rock surface. However, this is not uniquely a problem for NMR studies, but is a generic issue for all such studies on cores. Many measurements are made on cleaned samples where the reservoir fluids have been removed by flushing/solvent

extraction followed by resaturation with chosen fluids to allow the characterization of the required properties.

NMR has had a long history of application to the problem of characterizing fluids contained within porous rocks and other solids. Many of the relevant details may be found in other articles in this Encyclopedia, in particular *Well Logging*, *Imaging Techniques for Solids and Quasi-Solids*, and *Diffusion and Flow in Fluids*. This article is concerned solely with imaging of rock–fluid systems and will restrict discussion of the NMR properties of such systems to those required to understand the strengths and limitations of such investigations. No description of imaging principles is given and, again, relevant details will be found in the many articles in this Encyclopedia and in the referenced papers. Section 2 summarizes the basic NMR of fluids in rocks, whilst Sections 3 and 4 discuss the imaging of rocks saturated with one and two fluid phases, respectively. Section 5 outlines the application of NMRI to processes of importance to the oil industry.

2 NMR OF FLUIDS IN ROCKS

Most NMR studies of fluids in rocks have been carried out using ^1H nuclei and, unless otherwise indicated, this will be assumed. Oil reservoir rocks are of two main types: sandstones and limestones. Sandstones are predominantly comprised of silica grains which have often been considerably changed and cemented through diagenetic geological processes, such that they present a porosity which is usually less than 0.3. In addition, they may often contain many other mineral types and, in particular, clays which may be distributed within the basic silica-based porosity. There may also be a range of transition metal species present, particularly iron, and these can significantly affect the NMR response of fluids contained within the pore spaces. In sandstones, the pore spaces tend to be in the range of 0.1–100 μm , determined by the original silica grain size and the subsequent modification by geological processes. Limestones are predominantly calcium carbonate and the pore space can cover a wider range of scales, reflecting the biological origins and processes responsible for their formation. In particular, they may have some pore spaces which are as large as 1 mm in scale arising, for example, from the fossilization/dissolution of the shells of larger species trapped in the original matrix.

NMR imaging of oil reservoir rocks is carried out using the signals from the fluid phases and, to that extent, is similar to biomedical imaging. The differences lie mainly in the degree to which the solid matrix in which the fluids reside and move, together with the multiphase character of the fluids, affect their NMR properties. In addition, the fluid content is usually less than 30% of the sample by volume, which is smaller by a considerable margin than that of typical tissues imaged in biomedical studies. As a consequence, in most cases, the time required to achieve good signal-to-noise ratios will be longer. However, as long as the samples are not undergoing changes on the relevant timescale this is not a problem as rocks, unlike patients, are not concerned with how long they spend in the imaging system! The NMR properties which may be used for generating useful contrast in NMR images of fluid-filled porous rocks are, spin density, resonance frequency, spin relaxation processes, and the fluid transport processes of diffusion and flow. All of these

have been used, separately and in combination, to generate images of these systems. In the most general case, the fluids comprise gas, oil, and aqueous phases. The naturally occurring aqueous phases, usually referred to as ‘formation water’, have a significant ionic salt concentration which is reservoir-dependent. Typically, imaging experiments which require a replacement aqueous phase will use 3% NaCl brine. These aqueous ionic solutions can influence the tuning and quality factors of the rf coil systems and lead to rf attenuation effects within the samples. These effects should be taken into account when quantitative measurements are the goal.¹

2.1 Magnetic Susceptibility Broadening

The principal difficulty presented by fluid/rock systems in terms of NMR imaging is that, for many such materials, the transverse relaxation of the contained fluids can be strongly affected by magnetic susceptibility variations on the scale of the pore dimensions. This, combined with diffusion of molecules through these internal gradients, may lead to very rapid transverse relaxation for the spins in the contained fluids.² This effect is a strong function of the magnetic field strength of the NMR system used, in the worst case giving a T_2 value which varies as B_0^{-2} . As a consequence, the specifications required of the imaging spectrometer in order to achieve a representative signal reflecting all fluid present in the rock depend on the choice of operating field and can often exceed those which are readily accessible. Thus, there are a significant fraction of sandstones in particular for which quantitative measurements will prove impossible with conventional imaging techniques. Typically, when using the slice-selected 2D Fourier transform spin echo imaging sequence, for example, an echo time of 1 ms or less can be desirable and this places demanding requirements on the switching and settling times of the gradient systems, as well as on their maximum amplitude. Even with such short echo times, for some systems, only a fraction of the fluid will be detected. The reason that this is of concern is that, unlike some aspects of medical imaging, quantitative information is the ultimate goal when studying reservoir rocks.

The choice of magnetic field strength for imaging studies of fluid-saturated rocks is a compromise between the sensitivity and resolution required and the performance needed to overcome, as much as possible, the field-dependent T_2 effects referred to above. Many imaging studies of rocks have used a field strength of 2 T, corresponding to a ^1H resonance frequency of 85 MHz, and excellent quality images are achieved at this frequency. It is important, however, to recognize that these may reflect the properties of only a fraction of the fluid present and, for quantitative studies, this issue must be addressed directly. A further effect of these susceptibility contributions to the linewidth is to make chemical shift based discrimination of oil and water phases increasingly difficult as they get larger.

2.2 Surface-Enhanced Relaxation

In addition to the susceptibility effects, fluids contained within the pore space of reservoir rocks often show complex spin relaxation behavior (longitudinal and transverse),

which arises from enhanced relaxation when molecules find themselves at the rock–fluid interface. Diffusion is the usual process which brings molecules of a surface-wetting phase to this interface and the effect of this process is to make the relaxation times reflect the size scale of the pore space in which they are contained,^{3,4} see also *Well Logging*. The dependence of the relaxation times on this size can vary between linear and quadratic. In most sandstone rock systems it has been established that, for saturation with an aqueous phase alone, the so-called fast-diffusion limit applies⁵ making the contribution of this surface-mediated relaxation have the form

$$R_1 = (T_1)^{-1} \sim \rho(S/V) \sim \rho/a \quad (1)$$

where S/V is the surface-to-volume ratio of the pore space, a its linear dimension, and ρ the surface relaxation strength which has the units of m s^{-1} . The key relationship is that T_1 relates directly to pore size within this model. In most natural rock systems there exists a distribution of size scales within the fluid-containing space. As a consequence, the contributions of this mechanism of relaxation, particularly to spin–lattice relaxation for which it is usually dominant, generate a multiple exponential process. This can be treated in a number of ways, the choice of which will depend on the relationship between voxel size and the heterogeneity scale of the pore size distribution. At one extreme, when a voxel contains the full range of pore sizes, then if signal-to-noise (S/N) is sufficient, a regularized inversion to give a distribution of relaxation times (directly mapping onto a pore size distribution) could be used.⁶ For poorer S/N ratios, a fit to a stretched exponential is an alternative.⁷ At the other extreme then a single exponential fit may be appropriate, with the histogram of voxel relaxation times then revealing the distribution.

2.3 Fluid Transport

Both diffusion and flow are important processes for fluid transport within oil reservoir rocks and both can be used to generate contrast in NMR images of fluid-saturated rocks. The principles and practice of measuring diffusion effects and flow velocities may be found in a number of other articles in this Encyclopedia and the interested reader should consult these for the details,⁸ see, for example, *Diffusion and Flow in Fluids*. There are two main approaches to studying these processes. The main one is to use magnetic field gradient pulses to monitor the displacement of spins in the direction of the gradients. The range of timescales over which these displacements may be observed are dictated by the relaxation properties of the spins, while the amplitude of gradients available determine the spatial scales accessed. A second approach is to image the movement of an incoming or penetrating front which may be distinguished through some distinctive NMR property either present naturally or induced (see Section 2.4). These time-of-flight methods do not reveal the microscopic details of the process but can be simpler to implement.

2.4 Phase Discrimination

Imaging of two or more phases, present together within a porous rock, requires means of discriminating the signals from

those phases and there are a number of possible approaches. The choice available depends on the detailed characteristics of both the fluids and the containing rock. The principal methods are based on chemical shift or relaxation time differences, and can be either intrinsic or introduced. The chemical shift imaging methods used to discriminate water from fat in medical applications can be used to discriminate water and oil in rocks provided that the intrinsic transverse relaxation processes do not broaden the lines significantly beyond the shift difference and the oil phase is of low viscosity. Many crude oils have high viscosity and intrinsic linewidths which prohibit chemical shift imaging although, of course, a large difference in T_2 between the oil and aqueous phase will allow the aqueous phase to be detected uniquely. An extreme example of chemical shift imaging is the use of a substitute fluid which does not contain resonant spins, such as D_2O in place of H_2O , and, say, a fluorinated oil in place of normal oil. Spin-lattice relaxation-based discrimination is possible when the two phases have well-separated relaxation time characteristics. This can usually be achieved for water-wet rocks containing either light oil or heavy oil, which tend to give relaxation times longer and shorter, respectively, than the aqueous phase. If the spin-lattice relaxation characteristics of the two phases are too similar, then one or other may be changed by the introduction of relaxation agents, e.g. Mn^{2+} , in the aqueous phase or an oil-soluble molecule containing a nitroxide radical for the oil phase. Few of these approaches have been taken in practice in other than one-off investigations, so they cannot be regarded as well-established routines.

3 IMAGING OF ROCKS CONTAINING A SINGLE FLUID PHASE

With the development of actively shielded gradient coils⁹ almost all imaging of fluids in rocks has been carried out using slice-selected 2D or direct 3D imaging techniques, although some early work utilized projection-reconstruction methods.¹⁰ Usually, these are implemented on systems with 31-cm horizontal bore magnets with gradient coil sets and rf coils which allow for samples between core plug size (2.5–4 cm diameter) and whole core (up to 10 cm diameter). Preparation and containment of samples depends on the goal of the experiment. For simple porosity/ T_1 imaging, samples may be encapsulated, after saturation under vacuum/pressure treatments, with epoxy resin¹¹ or other plastic film coatings¹² to prevent fluid loss during imaging. Experiments which aim to study cores under dynamic or steady-state flow conditions, or under controlled temperature/pressure regimes, require the construction of core holders which can be inserted into the rf coils and, at the same time, allow the creation of the required flow/saturation conditions. Again, there is no universal design and these vary from resin-encapsulation to contain and constrain the fluid pressures and flow to more sophisticated designs employing radial hydrostatic pressure applied via a cylindrical sleeve in a so-called Hassler cell arrangement to achieve the same requirements.¹³

3.1 Imaging of Fluid Saturation/Porosity

The measurement of the spatial distribution of fluid saturation for a single phase requires the use of porosity

Figure 1 Porosity images of a cluster of four rock samples determined by extrapolation to zero time of a series of T_2 -weighted images. Slice thickness was 3 mm. A 20% porosity standard is imaged at the center with a porosity gray scale defined at the left-hand side. (Reproduced by permission of the Society of Petroleum Engineers from Edelstein et al.¹⁴)

standards as described by Edelstein et al.¹⁴ These workers used Cu^{2+} -doped H_2O/D_2O agarose gels as standards, allowing control of the volume concentration of 1H spins, T_1 and T_2 , as required. Using slice-selected 2D spin echo imaging, with echo times between 3 and 12 ms, they showed that they could determine the spatial distribution of fluid-filled porosity by extrapolation of the image intensities back to zero time. Figure 1 shows the resulting images for four samples together with a porosity standard and a gray-scale porosity reference scale. The only real check on the quantitative accuracy of such porosity images is to integrate the data over the image slices and compare the result with bulk measurements of the NMR porosity, calibrated by an independent determination of porosity using standard laboratory methods. Chen et al.¹¹ extended this T_2 -extrapolation approach to obtaining quantitative porosities/fluid saturations. Using as many as 15 different echo times, covering a range which gave signal attenuations greater than a decade, they investigated the use of a number of models of the transverse relaxation process, including single and multiexponential, and the stretched exponential, to perform the required extrapolation. They found, for the small number of samples they studied, that the best agreement with porosities determined gravimetrically was obtained using a double exponential model for the transverse relaxation of each voxel. There are, of course, significant time penalties to be paid to carry out such detailed multiimage extrapolations. However, if truly quantitative measurements are required, then an element of such calibration of the systems under investigation will be necessary in most cases. The use of a double exponential model was also endorsed by Fordham et al.¹⁵

Figure 2(a) is a cut-away view of a 3D porosity image of a North Sea sandstone saturated with 3% NaCl brine. This was obtained with an echo time of 1 ms and voxel dimensions of 0.3 mm. Figure 2(b) is a histogram of the distribution of porosity derived from the image in Figure 2(a) using a calibrated porosity standard without extrapolation. The mean of the distribution is 0.23 which is close to the value measured

Figure 2 (a) A cut-away view of a 3D porosity image of a brine-saturated North Sea sandstone together with (b) the calibrated porosity histogram derived from the complete image. The independently-determined porosity of this sample was 23%, which agrees closely with the mean of the histogram. (Data supplied and reproduced by kind permission of A. Hardwick and D. R. Roberts, BP Research and Engineering Centre, Sunbury-on-Thames, UK)

using conventional techniques. For this sample, then, the NMR methods used are seeing essentially all the aqueous fluid contained within the rock. As already mentioned, this is by no means always the case. The histogram of Figure 2(b) gives a useful, if limited, statistical view of the nature of the spatial porosity distribution. However, as pointed out elsewhere,¹⁶ there is a considerable amount of such information contained in the data set, of which Figure 2(a) is an example, which is not captured in any quantitative manner by these displays. A clear challenge for the future will be to characterize these complex structures, revealed by such fluid saturation spatial distributions and other image contrast mechanisms, using more sophisticated statistical treatments. The examples given in Figures 1 and 2 were of brine-saturated sandstones. Figure 3

Figure 3 A 2D slice-selected ^1H density image of a brine-saturated carbonate rock which has a wide range of porosity, some of which is comprised of pores considerably larger than the image resolution. The porosity scale covered by this image is between 1–100%. The image resolution is $3 \times 0.5 \times 0.5$ mm. (Data supplied and reproduced by kind permission of A. Hardwick and D. R. Roberts, BP Research and Engineering Centre, Sunbury-on-Thames, UK)

shows a porosity image of a brine-saturated carbonate. This shows very clearly the considerably greater porosity range encountered in such rock types in comparison with sandstones. The voxels in this image show porosities spanning the range 1–100%. The latter are represented by the large white areas of the image and arise from the presence of so-called vugs. A further example of imaging of larger-scale porosity in limestones is illustrated in Figure 4.¹⁷ In this case, a 3D image data set is displayed using a computer program which enables the porosity to be viewed from different angles. On the basis of this investigation it was concluded that there was only one connected path through this particular sample, an observation which was borne out by imaging fluid flow (see Section 3.3). It should be remembered that these measurements only yield this information because, for these limestone systems, the imaging resolution can be made less than some of the pore sizes.

3.2 T_1 Imaging

The imaging of spin–lattice relaxation is of value because of the relationship between T_1 and pore size, as discussed above. The T_1 images are usually obtained by prefacing the imaging pulse sequence with either an inversion–recovery or a saturation–recovery sequence, with images being determined as a function of the recovery interval. The data for each voxel

Figure 4 A 3D reconstruction of the porosity distribution inside a water-saturated limestone. Each image is of the same data but viewed from different angles by the rotations indicated. The 3D data set was constructed from a series of adjacent 2D slices. (Reproduced by permission of the publisher from Gleeson and Woessner.¹⁷ © 1991 by Elsevier Science Inc.)

in the image can then be fitted to an appropriate model for the spin-lattice relaxation process (see Section 2.2). Figure 5(a) and (b) show corresponding T_1 and porosity images for the same brine-saturated sandstone for which the full 3D porosity image was given in Figure 2. In this case, the experimental data for each voxel have been fitted to a single exponential recovery and lead to both a T_1 and an extrapolated M_0 (porosity) value for each voxel. These images are of a central slice of the cylindrical rock sample with a slice thickness of 3 mm and an in-plane resolution of 0.5 mm. This sample has a shale band running diagonally from near 10 o'clock to around 4 o'clock and it is clear that the T_1 image reveals this with more contrast than the M_0 image. This is because the shale bed, whilst having significant porosity, has a smaller pore size on average than the other porosity. This means that although there is significant fluid content in this bed, the T_1 value is considerably reduced. Similar differences in contrast are seen in the lower left parts of these images. As indicated above, the amount of information available in such images has yet to be fully exploited in even a semiquantitative manner.¹⁶ (The images shown in Figure 5(c) and (d) are discussed later—Sections 3.3 and 4.3.)

3.3 Diffusion and Flow Imaging

As already indicated, there are two basic approaches to the characterization of transport processes,¹⁸ see also *Diffusion and Flow in Fluids*. The first of these are time-of-flight methods which measure the appearance or disappearance, in a particular spatial location, of fluid spins which have been selected or saturated elsewhere. An example of this is the study of such flow-weighted imaging in a limestone.¹⁷ Figure 6 shows the normal and flow-weighted images of the same water-saturated limestone plug. The flow-weighted image was obtained using a 2D method which saturates stationary spins and generates signal only from spins flowing

into the imaged region on the repetition timescale of the sequence. It is clear from these images that only one of the several regions of significant porosity apparent from the porosity image (see Figure 4) contributes to fluid transport through this particular core plug.

Imaging of fluid velocity can, of course, be achieved directly using pulsed magnetic field gradient techniques to encode the displacements of the spins and coupling this with a suitable imaging procedure,¹⁸ see also *Diffusion and Flow in Fluids*. Typical results of such investigations are shown in Figure 5(c). This is a slice-selected image, obtained with a 2D FT technique incorporating two gradient pulses to encode the flow along the axis of the cylindrical rock sample, of the same sample used to generate the images of Figure 5(a) and (b). Whilst such 'velocity' images are relatively easy to measure, there are still a number of important issues which need to be addressed before quantitative data can be guaranteed. These issues are similar to those involved in the imaging of perfusion in medical applications^{19–21} and relate to the time variation of velocity brought about by changes in pore size and direction of flow relative to the gradient direction. It is important to remember that this approach to characterizing fluid transport actually measures displacements (see *Diffusion and Flow in Fluids*) with the velocity being a derived quantity. It is only in the limit that the velocity remains constant over the flow-encoding period that an unambiguous interpretation in terms of velocity can be given. These questions have been summarized by Nesbitt et al.²² That said, the image shown in Figure 5(c) illustrates the strong heterogeneity in flow paths within this sandstone rock core and can be compared with the corresponding images in Figure 5(a) and (b). Strong similarities are apparent with both the M_0 and T_1 images, although some significant differences can be seen, particularly in the region between 7 and 9 o'clock. It should be recalled that the M_0 image reflects porosity within a voxel, while T_1 reflects pore size. Flow would be expected to reflect both of these, in that larger and connected pores will have a high conductance

Figure 5 Images of the central slice (3-mm thick; in-plane resolution, 0.5×0.5 mm) of the brine-saturated sandstone also illustrated in Figure 2: (a) (top left) and (b) (top right) are spin-lattice relaxation time and porosity maps, respectively. These two images are constructed from a fit of each voxel magnetization recovery, measured using a saturation-recovery T_1 imaging experiment, to a single exponential process. While similar rock structures are revealed in both images, the marked differences arise because of the dependence of the T_1 value on pore size, as discussed in the text. (c) (bottom left) and (d) (bottom right) are velocity images of fluid flow in the same rock under conditions of (c) $S_w = 1$ and (d) S_{wi} (irreversible water saturation; the fractional porosity left occupied by the brine phase when displacement of this by an oil phase, under given flow conditions, has reached a steady state). The velocity is encoded along the cylindrical axis of the sample (perpendicular to the page) and was achieved by flowing the fluid at a constant rate of 5 mL min^{-1} . For (c) the fluid was the normal brine solution. For (d) the flowing fluid is a model oil, kerosene, and the signal in this case is predominantly from the oil phase. It can be seen that oil flow as visualized by comparison of these two images is less extensive, which is consistent with the presence of the residual aqueous phase. In addition, the strong similarity of (d) with (a), the T_1 image, is consistent with the water-wet characteristics of this rock which would confine the oil to larger pores. Images (c) and (d) are discussed in Sections 3.3 and 4.3. (Data supplied and reproduced by kind permission of A. Hardwick and D. R. Roberts, BP Research and Engineering Centre, Sunbury-on-Thames, UK)

for fluid while small pores, corresponding to the shorter T_1 values, even if having similar total porosities in a voxel, are likely to have a lower fluid conductance.

The flow rates present in producing reservoirs are very low, corresponding to fluid velocities sometimes as low as 10^{-2} – $10^{-1} \text{ mm s}^{-1}$. The measurement of such low flow rates in the presence of internal magnetic field gradients, caused by the magnetic susceptibility heterogeneities, can require

special sequences of rf and gradient pulses. This can be illustrated by the use of echo planar imaging (EPI) methods to characterize the slow flow of water through porous rocks.²³ In this approach, velocity-encoding of the image for the slow fluid flow through the rock was achieved using a combination of a Carr–Purcell/Gill–Meiboom echo sequence with an applied gradient pulse sequence which allowed the build up of a cumulative phase shift of the transverse magnetization because of the flow in the applied gradients. This sequence is illustrated in Figure 7. At the same time as maximizing the phase accumulation from flow, this sequence significantly reduces the contribution to T_2 of diffusion through the internal gradients by keeping the pulse spacing small. The overall sequence for flow imaging concludes with an EPI sequence utilizing 180° rf pulses instead of the more usual gradient reversal echoes. This is required to overcome the significantly inhomogeneous nature of the lineshape. Figure 8 shows the results of the use of this sequence to image the flow of water flowing through a clean sandstone, Bentheimer.²³ In a further development of this study, Mansfield and Issa²⁴ have investigated the quantitative behavior of the flow velocity distributions generated as a function of the pressure difference driving the flow. They have proposed a model to explain the observed behavior which, inter alia, suggests an explanation for their observations that the precise flow pattern seen in an image slice perpendicular to the main flow direction is not reproduced in detail on stopping and restarting the flow.

Despite the importance of diffusion, and the well-documented ability of NMR to characterize both structure and transport via its effects (see *Diffusion and Flow in Fluids*), imaging studies of fluid-saturated rocks using diffusion effects for contrast have been limited. Gibbs et al.²⁵ determined self-diffusion coefficient images for two brine-saturated cores (one sandstone and one limestone). They interpreted their results in terms of a reduction in the diffusion coefficient brought about by hindrance of the molecular displacements by the pore surfaces. The difficulty with diffusion imaging is that to take full advantage of the potential of the pulsed field gradient methods requires a wider range of gradient strengths than are usually found on imaging systems. This is particularly true when the intrinsic relaxation processes of the fluid spins are efficient.

4 IMAGING OF TWO-PHASE FLUIDS IN ROCKS

There are a number of approaches to obtaining spatially-resolved information from rocks containing more than one fluid phase. As already discussed, the essential discrimination methods which allow the images from the different fluid components to be separated are usually chemical shift or relaxation time differences, or some method of introducing such contrast via use of dopants or substitute fluids which, for example, give no signal.

4.1 Chemical Shift Resolved Imaging

In general, the line broadening found in rocks precludes the use of simple chemical shift imaging, although in favored cases it is possible.^{14,26} Figure 9 shows oil and water images for a carbonate rock, containing both oil and water phases, obtained using standard chemical shift imaging methods.²⁷ It shows the

Figure 6 NMR images of the same slice of a limestone sample saturated with water showing (a) the porosity distribution and (b) the fraction of the fluid-saturated porosity which can flow under applied pressure. The method used to detect the movable fluid involved saturation of the NMR signal so that only regions of fluid receiving magnetization from outside the saturated volume on the timescale of the experiment would give a signal. (Reproduced by permission of the Society of Petroleum Engineers from Gleeson et al., *SPE Form. Eval.*, 1993, 123)

Figure 7 The flow-encoding pulse sequence used, together with an echo planar imaging sequence based on 180° rf pulses, to generate the flow image shown in Figure 8. The combination of field gradient pulse sign alternation and reflection symmetry around the midpoint, together with even echo selection in the Carr–Purcell/Gill–Meiboom rf pulse sequence, maximizes the phase shifts produced by flow through the applied gradients, eliminates phase shifts arising from flow through internal field gradients, and minimizes the effects of diffusion through the same internal field gradients. These latter are caused by the magnetic susceptibility differences within the fluid/rock system. (Reproduced with permission of Academic Press from Guilfoyle et al.²³)

presence of a large fracture which, in this case, is not cemented and hence contains fluid, predominantly water. The largely complementary nature of the two images is readily apparent. In cases such as this, chemical shift resolved imaging should be a powerful tool for characterizing the spatial distributions of both immiscible fluid saturations and, via relaxation and transport-contrast methods, the quantitative details of the pore sizes accessed by the different phases and the various displacement processes, such as imbibition, drainage, and pressure-driven flow.

In general, however, chemical shift imaging has not found extensive use because of the limitations of spectral resolution. However, a method developed by Horsfield et al.²⁶ has extended the scope of this approach by using a model of the line-broadening mechanism, based on the magnetic susceptibility and shape of the sample, together with an assumed form for the underlying spectrum, to estimate the best values for the separate chemically shifted images. Their

method utilizes a set of images obtained for a range of free precession times (see Figure 10) which, at their extreme, produce a phase shift of 180° between the assumed oil and water resonance frequencies. Figure 11 shows a set of images reconstructed using these principles and for which the corresponding spectra were considerably overlapped.

Figure 8 The fluid velocity image for a longitudinal slice (flow direction from left to right) through a cylindrical sample of Bentheimer sandstone. The saturating/flowing fluid was water. Slice thickness was 10 mm with in-plane resolution of 3×3 mm. The image is the result of 16 averages of the sequence shown in Figure 7 with a flow-encoding time of 42 ms. The integrated flow at each point along the image axis is shown above the image. While this is constant, significant variations are seen in the image. In particular, regions of higher velocity are seen at the either end of the sample consistent with the single entrance/exit points of the flow cell used. (Reproduced by permission of Academic Press from Guilfoyle et al.²³)

Figure 9 Chemical shift resolved images of the brine and oil phase distributions within a preserved carbonate rock core. The large fault running from top left to bottom right is shown to contain largely the aqueous phase with the smaller porosity in the rest of the sample having complementary phase contents, i.e. large oil content is associated with low water content and vice versa. (Reproduced by permission of the publisher from Davies et al.²⁷ © 1994 Elsevier Science Inc.)

4.2 Phase Discrimination via Spin–Lattice Relaxation

For most rock–fluid systems, the voxel size employed in imaging of core-size samples is considerably larger than the underlying pore sizes. In these circumstances, the NMR signal from each voxel, for systems saturated with two immiscible fluids, will contain contributions from each fluid. In order to separate these contributions using the spin–lattice relaxation properties, these have to be sufficiently different. In practice this means they must differ by at least a factor of three in relaxation time. Crude oils can vary very significantly in their intrinsic spin–lattice relaxation properties²⁸ and the aqueous phase can show a wide variation in its relaxation behavior dependent on the pore sizes, whether the rock surface is water-wet, and on the relative saturations in the rock of each phase.²⁹ As a consequence it is not possible to offer a general prescription and each case has to be treated individually. In some cases a clear and quantitative separation is possible and Figure 12 shows a set of spin–lattice relaxation-resolved images for the same preserved carbonate core which was used to generate the chemical shift images shown in

Figure 10 The pulse sequence for phase-encoded chemical shift imaging. The time interval τ allows the development of a phase shift between different precession frequencies. (Reproduced by permission of Academic Press from Horsfield et al.²⁶)

Figure 11 A series of chemical shift resolved images of a sandstone in different states of saturation, the saturating fluids being water and dodecane. The images were obtained with the sequence illustrated in Figure 10 using the modeling technique of Horsfield et al.²⁶ for systems with strongly overlapped spectra. Images on the left-hand side of the Figure are of the aqueous phase protons; those on the right of the dodecane protons; (a) and (b) are of the rock in its fully water-saturated state, (c) and (d) following displacement with dodecane, and (e) and (f) following further displacement with KCl solution. (Reproduced by permission of Academic Press from Horsfield et al.²⁶)

Figure 9.²⁷ This sample had oil and water saturations of 0.43 and 0.56, respectively. In this case, the relaxation times of the oil and aqueous phases differ by an order of magnitude and the saturation–recovery data for each voxel were fitted to a double exponential process to extract the relaxation times for each phase. The images show clearly the considerable variation of the oil and brine saturations along the core plug. The slice shown in Figure 9 corresponds to the first slices in the middle rows of the image sets in Figure 12. It can be seen that the same features may be distinguished in both shift-resolved and relaxation-resolved images.

4.3 Flow Imaging with Two Immiscible Phases

The direct imaging of fluid displacements/velocities when two fluid phases are present requires, in principle, that separation of signals from the two phases be achieved using either of the techniques discussed in Sections 4.1 and 4.2, or the deliberate removal of the signal from one of the phases via doping with relaxation-enhancing agents or nonresonant spins. If the latter approach is adopted then this reduces the imaging experiment to effectively a single-phase measurement. Figure 5(d) is a velocity image of the same slice of the same rock used for the other images in Figure 5. In this case, the rock

Figure 12 NMR images of oil and aqueous phase distributions in the same carbonate core sample used for Figure 9. In this case the separation of the signals from the two phases was achieved through the differences in their spin–lattice relaxation behaviors. A saturation–recovery spin–lattice relaxation imaging experiment was used to acquire the data, with the magnetization recovery for each voxel being fitted to a double exponential process. The amplitudes of these two processes can be identified with the amounts of the two phases present and are used to generate the images shown. These are a succession of transverse slices along the cylindrical sample axis. The images shown in Figure 9 correspond to the first (left-hand side) image in the middle rows of the two sets shown in this figure. (Reproduced by permission of the publisher from Davies et al.²⁷ © Elsevier Science Inc.)

(initially saturated with brine) has been flooded with an oil to achieve a state of irreducible water saturation (S_{wi}) at the flow rate used, 5 mL min^{-1} , which is the same flow rate used for the single-phase flow image of Figure 5(c). At S_{wi} the flowing oil has removed all the water it can and, because this is a water-wet rock, the remaining water occupies the smaller pores and

will not be moving. Because of these factors this image is of the oil-phase flow only. Comparison of this image with that of Figure 5(c) shows that the oil flow is not as extensive as that of the water at $S_w = 1$ (complete saturation with brine). In addition, the oil-flow image has clear similarities with Figure 5(a), the T_1 image. This would be expected as the oil occupies, and flows through, the larger pore spaces and it is these which have the larger T_1 values.

5 IMAGING OF OIL INDUSTRY PROCESSES

In this section examples will be given of how the imaging capabilities outlined above have been used to investigate a number of processes which are utilized or encountered in oil industry operations. The industry has not, in general, taken a significant and coherent approach to the use of NMRI and the examples given in this section are the result of small groups of researchers in both industry and academic institutions who have attempted to demonstrate the ability of NMR to address phenomena and processes of importance.

5.1 Fluid Displacement

The central feature of hydrocarbon production is, of course, the relative movement of the oil and aqueous phases through the rock. This is a complex process and takes place under a range of conditions, either naturally occurring or engineered. In general, both phases coexist on a microscopic spatial scale as well as on a reservoir scale. The ‘Holy Grail’ for production is to move out all the oil and none of the water at very low cost! Clearly this is not an attainable goal. The processes involved in the production thus require the stimulation of the flow of the fluids and this can be driven by a natural pressure drop, or by externally applied pressures generated, for example, by pumping water and/or gas into the reservoir. The processes occurring in fluid displacement are usually characterized as being drainage or imbibition, the former being when the invading phase is nonwetting and the latter when it is the wetting phase.

Chen et al.¹¹ have studied both primary imbibition and drainage using a combination of 1D longitudinal profile images and 1D projections of thin-slice images, for both limestone and sandstone rocks. For a limestone core, saturated initially with the oil phase, displacement with D_2O (imbibition) was followed via measurement of longitudinal 1D projections to determine the variation with time, and the volume of injected D_2O , of the oil saturation along the displacement direction. A key observation arising from this study is that the transverse relaxation characteristics of the signal, in this case arising solely from the oil phase, depend on the oil saturation to a significant degree. This could arise from the introduction of further magnetic susceptibility inhomogeneity at the pore scale.³⁰ The effect is estimated to lead to a reduction in derived saturations if not properly accounted for. Figure 13 shows a set of 1D profile images obtained by projecting the signal from a thin slice perpendicular to the fluid displacement direction onto an axis in the slice plane parallel with the main bedding planes of the laminated structure of this rock. The profiles represent the oil saturations at different times in the process of imbibition of D_2O into this, originally, fully oil-saturated

Figure 13 The evolution of 1D projection images of a laminated sandstone undergoing imbibition in which the oil phase, which gives rise to the signal, is spontaneously replaced by the wetting phase, water (D_2O). The signal decreases as the D_2O enters the slice and, because of the choice of orientation of the sample with respect to the gradient, the differential rates of transport in the different bedding planes can be discerned. The timescale spanned by the different curves is 192 min from the start of water injection. (Reproduced by permission of the Society of Petroleum Engineers from Chen et al.¹¹)

sandstone. Analysis of the set of images from slices along the full length of the core indicated that fluid is displaced at significantly different rates in the different layers, which was interpreted as indicating significant permeability variations in the different planes of the structure. Similar slice-profile images, taken under different steady-state flow conditions, showed that for the imbibition process all the mobile oil was displaced at the lowest flow rate whereas, for the subsequent drainage process in which oil is used to displace D_2O , the oil saturation continued to increase with flow rate throughout the range investigated. It was deduced, also, that there was no significant variation of wetting behavior across the laminated structure of this sandstone.

Related investigations of fluid displacements have been carried out by other groups^{12,13,15,32} and, whilst it is clear that these processes can be probed using the versatility of NMR imaging experiments, there remain the problems of signal-to-noise ratio/resolution, fast transverse relaxation, and the variation of this with saturation. These offer a considerable challenge to the NMRI/petrophysics communities if they are to capture the full potential of this combination in a quantitative manner.

A study by Fordham et al.¹⁵ goes a long way towards meeting that challenge and, to a degree, extends the approaches of Chen et al.¹¹ and Enwere and Archer.³² These workers again use D_2O together with an oil phase (*n*-dodecane) to make a quantitative study of oil saturation variations along the length of a core. In this case the displacement of the wetting phase, D_2O , by the oil phase (drainage) was investigated under the conditions that the outflow end of the rock was held at $S_w = 1$. The cell used, which was mounted vertically in the horizontal magnet bore, is shown in Figure 14 while the derived spatial variation of oil saturations and T_2 values as a function of flow rate are given in Figure 15. This study was aimed at validating a method which had been proposed for the study of two-phase flow under these conditions, which it succeeded in doing. This

Figure 14 The sample cell used by Fordham et al.¹⁵ to study the drainage process in a sandstone rock. The wetting phase (D_2O) is displaced by oil with the end of the sample held at $S_w = 1$. In this case the sample axis was mounted vertically within the horizontal magnet bore. The diagram shows clearly the arrangements for the generation of a reference signal, the lateral pressurized fluid containment, and the maintenance of the condition $S_w = 1$. is probably the only example where a strong and quantitative link has been established between the complex fields of NMRI and petrophysics.

5.2 Drilling Mud Invasion/Depth Filtration

Drilling muds may contain particulates such as clays which are small enough to penetrate the rock formation being drilled. The timescale and extent of such penetration is of interest and NMRI has been used to investigate this phenomenon.^{33,34} The basis of the approach is that the T_1 value of the fluid contained within the rock is reduced by the addition of fine clay particles. An earlier study of filtration³⁵ established the relationship between an average measure of the spin-lattice relaxation time and the local 'concentration' of the filtered solid particles. In one study³³ penetration of bentonite particles into rocks of different pore size and permeabilities were imaged and it was shown that the T_1 profiles reflected the presence of the clay and the extent of its penetration. In a further study³⁴ the same process was observed dynamically using a fast imaging method called 'prefocused FLASH'. Figure 16 shows a series of such images showing the time course of the penetration of the clay into the rock. The main changes occur over a time interval of 15 s and these images illustrate the potential of NMRI for the investigation of the dynamics of such processes.

Figure 15 The 1D image profiles for the drainage process referred to in the text and in Figure 14. The upper set of profiles are the oil saturation along the length of the rock core while the lower set are of the corresponding T_2 values, each data set corresponding to different volumetric flow rates. An important observation from these data is the clear variation of T_2 of the oil phase with saturation. 6 SUMMARY

NMRI studies of fluids in porous oil reservoir rocks are at a stage of development where, to a large extent, the measurement techniques with their attendant strengths and limitations have been explored and the underlying NMR physics defined in many aspects. This, coupled with studies on model and related systems,^{22,36,37} will only make a real contribution to oil industry problems through a dedicated and collaborative effort between NMRI specialists and reservoir engineers and petrophysicists.

1 INTRODUCTION

Nuclear magnetic resonance in weak B_0 fields (of the order of magnitude of the terrestrial magnetic field B_T) has only a modest place in this area of nuclear magnetism. One sometimes imagines that such experiments are without any real specific interest; our objective here is to state the interest these experiments have as precisely as possible. Sometimes they are simpler or more efficient than experiments with strong fields and in some cases strong field experiments cannot be performed at all.

After having compared these areas of application of NMR we will recall the important results obtained with weak fields, both on the fundamental level and in applications.

2 THE CHARACTER OF NMR IN THE TERRESTRIAL MAGNETIC FIELD (SEE)

2.1 The Field B_0

2.1.1 The Terrestrial Magnetic Field B_T ¹

The terrestrial magnetic field is dipolar, its direction in our neighborhood varying by only a few degrees from the geographic N–S. It is of weak amplitude, between 2.5×10^{-5} and 7.5×10^{-5} T, and about 5×10^{-5} T in temperate regions. Its interest lies in its large homogeneity and slow diurnal and secular variation for suitably chosen sites, this allowing measurement at a precision of 10^{-10} T.

2.1.2 Additional Fields

The use of the terrestrial magnetic field does not usually allow one to avoid superposing either an additional positive or negative field to change ω_0 or a gradient. Such a gradient can be obtained, for example, by supplying two identical, parallel, coaxial coils wound in opposite senses with a continuous current i . Variation of i allows one to vary the homogeneity at the center of symmetry of the system in a calculable way. (See *Field Gradients and Their Application*.)

2.2 Lack of Information

2.2.1 Weak Field Strength

The small amplitude of the terrestrial magnetic field implies a weak nuclear polarization. For a nucleus with magnetic moment μ placed in the terrestrial field B_T at absolute ambient temperature T , the ratio between the number of dipoles parallel to the field and those antiparallel is given approximately by the expression $1 + 2(\mu B_T/kT)$, which has a value of about $1 + 3 \times 10^{-10}$ (k = Boltzmann constant). Here we understand why NMR was discovered with fields in the range 0.2–0.7 T and why the fields used these days can attain or surpass 17 T. One often overcomes the handicap of a weak amplitude by prepolarizing the nuclei with a strong field.

2.2.2 Exploration Restricted to Narrow Lines

B_T not being greater, on average, than 5×10^{-5} T, one can only easily observe and study lines of a width less than 10^{-7} T. However, this condition is not sufficient as one must choose nuclei with a large gyromagnetic ratio γ , which are of spin- $\frac{1}{2}$ (to avoid quadrupole broadening) and which are present in a large density in the sample. This excludes notably solids, paramagnetic media, and liquids trapped in porous media that are too fine.

2.2.3 Lack of a High Homonuclear Resolution

This resolution is governed by the chemical shift δ and the indirect interaction constant J between the nuclei. If the nuclei are all the same, then δ tends to zero for a weak field as does the amplitude of the satellites due to J . For example, ethanol has only one spectral line in B_T whose width depends only on the relaxation times T_1 and T_2 .¹ Everyone knows the complicated spectrum of this compound in a high field.

2.3 Positive Aspects

2.3.1 Measurement and Study of the Terrestrial Magnetic Field

The first spectrometers were built with the measurement of B_T in view. This approach seems to have been abandoned these days.

2.3.2 Samples Not Readily Accessible or of Large Volume

One of the applications of NMR in the terrestrial field is the geophysical exploitation of underground deposits: either by spectrometric investigation of bore holes or with spectrometers resting at ground level used to search for underground water reserves.

2.3.3 Study of Fundamental Phenomena in NMR Not Easily Accessible at High Field

It is relatively simple to study separately the diverse parameters which characterize NMR and the effects of a change in these parameters:

- Amplitude and homogeneity of B_0 ;

- Speed of crossing resonance, modulation of B_0 ;
- Nonlinear effects (when B_1 is not orthogonal to B_0);
- Application of a nonresonant rf field B_1 ;
- Separate study of the two rotating components of B_1 both at and away from resonance.

2.4 Terrestrial Field Spectrometers

One can use both spectrometers of the same type as those employed for high fields, adapted for low frequencies, and apparatus using a different principle (with prepolarization). Special techniques have also been used for particular problems.

2.4.1 Conventional Spectrometers

The first observations of proton NMR in the terrestrial magnetic field were made either with a crossed coil spectrometer (the need for a large S/N ratio requires that particular care be taken with the receiver coil having a 2 L volume) or with a single coil (useful volume, 8 L).²

The working frequency was in the neighborhood of 2 kHz, the coil surrounding the sample having a large number of turns: care must be taken to reduce the interlayer capacitance to a minimum.

One must note an original type of spectrometer brought into operation by a Russian–Australian collaboration.³ Here the sample is an underground permeable layer filled with water, either stagnant or flowing. One lays a circular coil of large diameter on the ground linked to a powerful high-frequency generator or a detector tuned to the Larmor frequency ω_T of protons in the local terrestrial field.

Knowing the value of B_T , a strong B_1 field pulse at the frequency ω_T is sent by the coil. This has the effect of aligning the magnetic moment M_T in the plane perpendicular to B_1 . After the pulse is finished, the vector M_T precesses around the direction B_T at the frequency ω_T . The same coil serves to receive the signal.

According to the authors, one can detect water at a depth of the order of magnitude of the coil diameter (at present around 200 m). The telluric currents are the main cause of noise.

2.4.2 Spectrometers Using Prepolarization

2.4.2.1 Permanent regime. The sample, a liquid circulating around a closed circuit, passes first through an intense magnetic field B_P , where the nuclei are strongly polarized. It then arrives in the field B_T , where the NMR signal is observed. For this system to be useful one must suppose that the time t spent in the field B_P is long enough ($\approx T_1$) and that spent between B_P and B_T is smaller than the effective relaxation time T'_2 of the nucleus studied.

2.4.2.2 Dynamic regime. The sample is placed in a coil B whose axis is perpendicular to the direction of the terrestrial field B_T . The measurement is made in two stages:

1. The coil is supplied with a continuous current i_P strong enough to give an M_P polarization proportional to i_P and directed along the coil axis. A large polarization will result if the polarization time t is of the order of magnitude of T_1 .
2. The current i_P is suddenly cut and the coil linked to a receiver tuned to the frequency ω_T . A decreasing signal is detected:

- whose initial amplitude is proportional to M_P ,
- whose frequency is ω_T ,
- whose decay allows the measurement of T_2 in B_T if the field is sufficiently homogeneous.

2.4.3 Special Techniques

2.4.3.1 Study of nuclear magnetism away from resonance.

Such a study is relatively easy using the technique of prepolarization before free precession. It suffices to apply a permanent rf field perpendicular to the direction of the terrestrial field after removing the polarizing field.

2.4.3.2 Inversion of reference system without resonant impulsion¹⁰. Spin echoes, discovered by E. Hahn and much studied since, are normally obtained using rf pulses at Larmor frequency with a suitably chosen length, periodicity, and phase, and directed along an axis perpendicular to B_0 . The effect of these pulses is always to produce artificial ‘time reversal’, which is the origin of the resetting in the phase of the nuclei and the resulting echoes.

In the constant and homogeneous terrestrial field it is easy to superpose a gradient whose inversion can be equivalent to a resonant pulse π .

2.4.3.3 Relaxometry⁴ (see *Field Cycling Experiments*).

The essential aim of this technique is to measure the size of the relaxation times T_1 , $T_{1\rho}$, and T_2 in a field B_R of different amplitude to the field B_0 for which one observes resonance, in order to measure the correlation times τ_c at the origin of the relaxation. When $\omega_0^{-1} \approx \tau_c$ one has variations of the relaxation times as a function of the applied field B_R . It is better to evaluate $T_1(B_R)$ because T_1 only depends on those τ_c values longer than ω_0^{-1} , whereas T_2 and $T_{1\rho}$ are conditioned by all the τ_c values characterizing the explored medium. (See *Brownian Motion and Correlation Times*.)

Moreover, one finds that in many aqueous solutions, notably protein solutions and physiological fluids, T_1 is the most sensitive relaxation time in the range 10^{-2} to 10^{-7} T for B_R . Such small values for B_R may be larger or smaller than the terrestrial field B_T and it is a very simple matter to describe the curve $T_1(B_R)$ which consists of:

1. polarizing the nuclei of the sample in the field B_P to obtain the polarization M_P .
2. measuring $T_1(B_R)$ by submitting the sample to the field B_R for a variable length of time. The decrease of $M_P(B_R < B_P)$ with increasing time during which the sample is subjected to the field B_R allows one to observe, at the cutoff of B_R , the free precession of the magnetization M_P : the initial amplitude of this signal allows the calculation of $T_1(B_R)$ and its exponential decay allows the evaluation of T_2 in the terrestrial field.
3. making the measurements for a series of values of B_R with the aid of an additional field superposed with B_T and either parallel or antiparallel to it.

3 UTILITY OF TERRESTRIAL FIELD NMR AT THE FUNDAMENTAL LEVEL

3.1 Historical Digression: Negative Results²

We will not insist on the questions that were usually asked during the first years following the discovery of NMR, but

Figure 1 Benzene dispersion with $B_1 \approx 1.5 \times 10^{-10}$ T

which were then found to be without interest. The relation $\omega_0 = B_0\gamma$ is verified even for very weak fields. There is no particular interaction between the spins of the dipoles of an electromagnet and nuclear spins. The indirect interactions J between spins are as simply explained in weak fields as in strong ones.

3.2 The Width of the Narrowest Resonance Lines

As soon as proton resonance was observed in the terrestrial field B_T , the homogeneity and constancy of this field in suitable locations was exploited to investigate the natural width of the narrowest spectral lines. The measurement of the proton relaxation time in benzene allowed the prediction of a linewidth not exceeding 2.4×10^{-10} T. Figure 1 shows the experimental result of G. Hochstrasser.¹¹

3.3 Perturbations due to B_0

3.3.1 Line Broadening by Inhomogeneity

The precise calculation of the inhomogeneity of the field B_0 over the sample volume, when this field is produced by two Helmholtz coils and one moves the sample along the axis starting from the symmetry center of the system, allows the precise evaluation of the influence of inhomogeneity on the resonant linewidth.²

3.3.2 Modulation Effects

The field B_0 is often superposed with a swept alternating field of frequency Ω and amplitude B_M . Rocard⁵ precisely analyzed the effects of such modulation when $B_0 = 2 \times 10^{-4}$ or 7×10^{-5} T. The spins ‘see’ the frequency spectrum $\omega \pm k\Omega$ and therefore the transitions $\omega \pm k\Omega = \gamma B_0$. The relative phase of B_1 and B_M gives a large variation in the shape of the resonant signal.

3.3.3 Time-Varying Inhomogeneity: Spin Echoes Without Resonant Pulses²

Reference frame reversal by inversion of the field B_0 or its inhomogeneity can be simply realized by supplying the generating coil with a ‘pure gradient’ by an alternating field. In the free precession after the prepolarization technique, the cutting of the polarizing field B_P is equivalent to a resonant $\pi/2$ pulse. Inverting the gradient of the field B_T (by inverting the current direction in the coils) is equivalent to a π pulse in the usual spin echo technique. It is much simpler to study the gradient-generating coils with an alternating current: here the reference frame inversion is achieved by time-dependent pulsation (Figure 2).

Figure 2 Spin echoes in an alternating gradient

3.4 Perturbations to the Rf Field B_1

3.4.1 Resonant Linewidth Broadening

The homogeneity of the terrestrial magnetic field allowed Hochstrasser¹ to evaluate precisely the influence of the amplitude of B_1 on the width and form of the proton resonance: he showed that this perturbation did not affect the form (Lorentzian central part) but determined the linewidth.

3.4.2 Nonlinear Effects¹²

Pommier and Benoit studied the influence of angles θ (between B_0 and B_1) different from $\pi/2$ at $\omega_0 = 3$ kHz. Application of the Bloch equations predicts resonances for $\omega_0 = n\omega$, which translates at first order to the Bloch–Siegert shift and generation of harmonics as well as sidebands [$\omega_0 = (n \pm 1)\omega$].

3.4.3 Effect of a Nonresonant Field B_1 ²

Using the technique described in Section 2.4.3.1, after removing the polarizing field B_P the magnetization M_P is subjected to the field B_T which is superposed with a perpendicular nonresonant field B_1 of frequency ω , which is either rotating or alternating. In each case one determines the pulsations of the free precession phenomenon observed in B_T . If one has a rotating field [either in the same sense as the nuclear precession (+) or in the opposite (–)] one has three solutions

$$(+) \omega, \omega \pm \sqrt{(\omega_0 + \omega)^2 + \omega_1^2}$$

$$(-) \omega, \omega \pm \sqrt{(\omega_0 - \omega)^2 + \omega_1^2}$$

where $\omega_1 = \gamma B_1$. With $\omega_0 = 2$ kHz, ω was varied between 500 and 4000 Hz. Figure 3 shows that the first-order effect of an alternating field reduces to the superposition of two rotating fields. For a sufficient intensity of the field B_1 one observes higher-order effects, notably transitions involving 3 quanta.

Figure 3 The nonresonant dispersion shift, in rotating and alternating excitation

3.5 Determination of Intra- and Intermolecular Parameters

3.5.1 Indirect Spin-Spin Interactions in Weak Fields² (See *Analysis of High-Resolution Solution State Spectra*)

As recalled above, only interactions between nuclei of different type are observed.

3.5.1.1 Nuclei of adjacent spin- $\frac{1}{2}$ atoms. Extending the work of Roux¹³ to weak fields, Erbeia¹⁴ analyzed the $J(^{31}\text{P}, ^1\text{H})$ interaction in a field $B_0 = 1.4 \times 10^{-4}$ T by the observation of a proton doublet in phosphoric acid (AB type spectrum) (see *Phosphorus-31 NMR*). The same author studied the AB₂ multiplet obtained in hypophosphoric acid. Our group has observed $^{13}\text{C}-^1\text{H}$ and even $^{15}\text{N}-^1\text{H}$ multiplets in the Earth's field and at natural concentration, in the latter case by using electronic dynamic polarization of ammonium ions. Figure 4 shows the quadruplet resulting from the $^{13}\text{C}-^1\text{H}$ interaction in methanol and the corresponding theoretical spectrum.

3.5.1.2 Nuclei of spin different to $\frac{1}{2}$ adjacent to protons. The Paris (F) group studied the $^2\text{D}-^1\text{H}$ coupling in a current of prepolarized HD liquid. A transition at $\nu_0 = 54$ Hz was

Figure 4 Proton quadruplet resulting from $^{13}\text{C}-^1\text{H}$ interaction in methyl alcohol at the natural concentration of ^{13}C

observed in a field $B_0 < 3 \times 10^{-6}$ T: the smallest Larmor frequency observed in condensed matter. The weak field interaction between ^{14}N ($I = 1$) and ^1H in the ammonium ion was first studied by J. M. Rocard¹⁵ at $B_0 = 2 \times 10^{-4}$. Merck¹⁵ demonstrated the second-order quadrupole $[J^2_{AB}/(\Delta_A - \Delta_B)]$ of 1.35 Hz (the first order corresponding to $J = 52.55$ Hz). (See *Overtone Spectroscopy of Quadrupolar Nuclei*.)

3.5.1.3 Nonadjacent spin- $\frac{1}{2}$ nuclei. E. Duval has studied the $^{31}\text{P}-^1\text{H}$ interactions in triethyl phosphate and triethyl phosphite in the positions P-O-C-H- α and P-O-C-C-H- β . He observed that the complex multiplet obtained allowed the evaluation of the interaction constants $J(\text{P,H-}\alpha) = 8.4$ Hz and $J(\text{P,H-}\beta) = 0.84$ Hz and was sensitive to the relative signs of these two coupling constants. (See *Indirect Coupling: Semiempirical Calculations*.)

3.5.2 Relaxation Dispersion of Proton Nuclei (See *Protein Dynamics from NMR Relaxation*)

It is well known that the relaxation time in mobile liquids depends essentially on the correlation times τ_c [or the correlation frequencies $\nu_c = (2\pi\tau_c)^{-1}$] defined by microscopic molecular motion or the lifetime of molecular structures in a given configuration.

It was found that, in water and many diamagnetic aqueous solutions of proteins or other organic molecules, the dynamics of these solutes appear as a correlation frequency spectrum covering the range 10^2 – 10^7 Hz. These correlation times can be directly studied by measuring the relaxation time of the solvent water, and in particular by measuring T_1 in the range of B_0 corresponding to $\nu_0 \approx \nu_c$. More precisely, if ν_0 is much greater than the largest ν_c then $T_1 = \infty$ or more simply $T_1^{-1} = 0$, whereas if ν_0 is much less than the smallest ν_c then $T_1 = T_2$. In the intermediate region T_1 changes more or less rapidly each time B_0 crosses a region where ν_0 is of the order of the magnitude of ν_c .

The relaxometry technique described above in Section 2.4.3.3 allows B_0 to be varied between 10^{-7} and 10^{-2} T. It has notably allowed the observation for the first time of the dispersion in T_1 due to the lifetime of H^+ and OH^- ions in water, without having to use ^{17}O enrichment (see *Oxygen-17 NMR*). On the same lines we have measured the dispersion of the proton relaxation time in diverse types of amides in solution (see *Relaxation Effects of Chemical Exchange*).

Finally, the study of proteins or other organic macromolecular solutions has shown an important dispersion of T_1 in the range 10^3 – 10^6 Hz. This dispersion is often a characteristic of the studied medium, whether it would be simple or complex, in solution or gel. Figure 5 shows the dispersion curve of an aqueous solution of human fibrinogen.^{4,6} This gives the possibility of application to medical diagnostics, as we will show later.

4 APPLICATIONS OF NMR IN THE TERRESTRIAL FIELD

4.1 Measurement of B_T

This application, which was largely developed in the 15 or so years following the first publication (1954), allowed the

Figure 5 Experimental and theoretical frequency dependences of T_1^{-1} (open circles) and T_2^{-1} (filled circles) in a fibrinogen solution

measurement of either the amplitude of the vector $\mathbf{B}_T$ or its gradient. It was then abandoned in favor of other techniques independent of NMR.

4.2 Search and Study of Underground Liquids (See *Geological Applications*)

NMR in the terrestrial field is studied for two types of application:

- In bore holes, by introducing a spectrometer which recognizes the crossing of layers rich in water or petrol (and in some cases allows the description of the fluid encountered and its environment with a certain precision) (see *Coal Structure from Solid State NMR*).
- From the surface, the spectrometer described in Section 2.4.1 (hydroscope) was used for layers at depths of up to 200 m, allowing the determination of the depth, thickness, and richness in free water of the layer. This technique is the subject of current research.³

4.3 Applications to Medical Diagnostics (See *Body Fluids*)

4.3.1 Measurement of Relaxation Times⁴ (See *Relaxometry of Tissue*)

Relaxometry allows the construction and comparison of the dispersion curves for the relaxation time T_1 of macromolecular solutions. As an example, the human body contains such solutions at different points, e.g. blood in the circulatory system, urine in the kidneys and bladder, ascite liquid, and the amniotic fluid of pregnant women. A pathological change in one of these liquids is sometimes indicated in a strong way in their T_1 dispersion curves.

We have undertaken such a study using prepolarization and free precession and shown, in situ, a change in the amniotic fluid when it is contaminated. Such a measurement was realized by placing the exploratory coil directly on the patient's abdomen. Clearly one chooses an optimum value of $\mathbf{B}_R$ which, in this case, is not critical.

4.3.2 Weak Field Imaging (See *Image Formation Methods and Low-Field Whole Body Systems*)

The university research groups of Lyon (F) and Ljubljana (SLO) have presented results on imaging: an apparatus using prepolarization, which is nearly ready for applied use, has been prepared by the latter. The images of phantoms exhibit a spatial resolution close to 2 mm.⁷ Self-diffusion and flow imaging were also successfully investigated⁸ (see *Diffusion Measurements by Magnetic Field Gradient Methods and Flow NMR*). Relaxation imaging, in which T_1 is measured in the polarizing field, and T_1 and T_2 in the Earth's field, is able to give better contrast than in high-field imaging⁹ (see *Relaxation Measurements in Imaging Studies*).

1 INTRODUCTION

Well logging is the means by which physical properties of subsurface earth formations are measured in situ. The most important, and the most technically challenging, application of well logging is to the characterization of hydrocarbon reservoirs. Oil and gas are found up to 10 km underground in beds of sedimentary or other porous rock. Only a part of a typical sedimentary rock is solid mineral matter. The pore space, which accounts for up to 30% of the volume, can be filled by combinations of oil, water, or natural gas. Well logging is directed toward understanding these fluids and their relationship to the solid mineral matrix. A large variety of electromagnetic, acoustic, and nuclear borehole instruments are used for various purposes. Each technique has drawbacks and limitations, and no one logging device ('tool') is adequate to give a complete description of an earth formation.^{1,2}

Measuring properties of earth formations in situ by NMR obviously requires apparatus very different than that commonly used in the laboratory. Instead of placing the sample inside the apparatus, the apparatus is placed inside the 'sample', which is in fact the earth. Thus 'inside-out' NMR equipment is required: large static magnetic fields and high-frequency oscillatory magnetic fields must be projected outside of the apparatus and into the surrounding rock formations. Moreover, the apparatus is normally in motion during the measurement.

The amplitude of the proton NMR signal is proportional to the fluid content of the rock, and relaxation times give information on the pore size distribution and, under favorable conditions, the amount and type of oil. These measurements are used by the oil industry to estimate the quantity of hydrocarbon in a reservoir and the rate at which it can be economically extracted. The application of NMR to well logging is the subject of an extensive bibliography, covering 1946–1990, compiled by Jackson and Mathews.³ The reader also is referred to review articles^{4,5} and proceedings of international conferences.⁶

Owing to limitations of signal-to-noise ratio, the only nucleus accessible to borehole NMR is hydrogen. Throughout this article, all statements refer to proton NMR. Nonuniformity of the static magnetic field precludes the acquisition of chemical shift spectra.

2 NMR RELAXATION PROCESSES IN ROCKS

2.1 Surface-Limited and Diffusion-Limited Regimes

NMR relaxation rates of fluids in porous media are enhanced by relaxation at the pore–grain interface.^{7,8} Fluid molecules diffuse, eventually reaching a grain surface, where they have a finite probability of being relaxed. The rate-limiting step can either be the relaxation process at the surface or the transport of unrelaxed spins to the surface.

If the rate-limiting step is relaxation at the surface, the nuclear magnetization in a pore is uniform. Therefore the magnetization decay in the pore is monoexponential and does not depend on pore shape but only on the surface-to-volume ratio of the pore. This is referred to as the 'fast diffusion' or 'surface-limited' regime.⁹

In the opposite case, magnetic relaxation occurs at the grain surface, but the decay of macroscopic magnetization is controlled by the transport of molecules to the surface. This is possible when pores are relatively large and/or surface relaxation is strong. This is called the 'slow diffusion' or 'diffusion-limited' regime. In this regime, magnetization in the pore is not uniform. This gives rise to a magnetization decay, which, in each pore, has multiexponential character, and which depends on the shape of the pore.¹⁰

Support for the surface-limited hypothesis comes from measurements of the temperature dependence of relaxation times in rocks.¹¹ Remarkably, T_1 and T_2 are nearly independent of temperature over the range 25–175 °C, at least for the modest number of rock samples studied. If NMR relaxation were in the diffusion-limited regime, the relaxation time would depend on the diffusion coefficient of the pore fluid, which is very temperature-dependent. The lack of temperature dependence is a mark of the surface-limited regime.

2.2 Surface Relaxation Mechanisms

The basic principles of NMR relaxation of fluids at solid surfaces in porous media were established by Korringa, SeEVERS, and Torrey (KST).¹² Two surface processes were identified. One occurs at all sites on the surface and the other is associated with dilute paramagnetic metal ion impurities on the surface. The relaxation process associated with nonmagnetic sites is much too weak to account for the observed relaxation of water in rocks.¹³ Paramagnetic ions, such as iron, manganese, nickel, and chromium, are particularly powerful relaxers, and tend to control the rate of relaxation whenever they are present. Rocks primarily composed of silica (sandstones) generally have an iron content of about 1%, and also frequently contain manganese in significant concentrations; these ions make fluid proton relaxation fairly efficient. Occasionally, sandstones contain grains of magnetic minerals such as magnetite (Fe_3O_4), which are sites of relaxation. In carbonate rocks, which are composed of calcite (CaCO_3) and related minerals, the rate of fluid relaxation tends to be lower than in sandstones.

Considering only relaxation by dilute paramagnetic ions, the KST equations for surface relaxation in a single pore reduce to

$$\frac{1}{T_1} = \frac{Sh}{V} \frac{n_M}{T_{1M}} = \rho_1 \left(\frac{S}{V} \right)_{\text{pore}} \quad (1)$$

where S and V are the surface area and volume of the pore, h is the thickness of the surface layer within which relaxation can take place, n_M is the proportion of surface sites occupied by paramagnetic metal ions, and T_{1M} is the relaxation time of protons in molecules coordinated with paramagnetic ions. All material constants are included in the surface relaxivity parameter ρ_1 , which has dimensions of m s^{-1} .

KST do not discuss T_2 in porous media. T_2 is shortened by $>$ molecular diffusion in the inhomogeneous magnetic field arising from the magnetic susceptibility contrast between grains and pore fluid (see Section 2.3), which is unrelated to surface relaxation. However, for proton Larmor frequencies below 5 MHz and for Carr–Purcell echo spacings less than about one millisecond, the enhancement of T_2 decay coming from diffusion in inhomogeneous local fields is often negligible compared with the surface relaxation mechanism. Then¹⁴

$$\frac{1}{T_2} = \frac{Sh}{V} \frac{n_M}{T_{2M}} = \rho_2 \left(\frac{S}{V} \right)_{\text{pore}} \quad (2)$$

The surface relaxation mechanism is treated in detail by Kleinberg, Kenyon, and Mitra.¹⁴ Briefly, the relaxation of fluid protons at paramagnetic ion sites on the surface of rock grains is controlled by the dipolar and scalar interactions between the ion and nuclear moments. Among other things, the theory explains why T_1 and T_2 are correlated at low frequency: $T_1 \approx 1.6 T_2$.

2.3 Molecular Diffusion in Magnetic Field Gradients

A second contribution to transverse relaxation is the diffusion of spins in static magnetic field gradients. In a uniform B_0 gradient, the contribution of this mechanism is

$$\left(\frac{1}{T_2} \right)_D = \frac{1}{12} D (\gamma G T_E)^2 \quad (3)$$

where D is the molecular diffusion coefficient, γ is the gyromagnetic ratio of the proton, G is the gradient strength in T m^{-1} , and T_E is the Carr–Parcell echo spacing. This equation is applicable to bulk liquids, for which the diffusion coefficient is a constant. In porous media, the diffusion coefficient is time-dependent,¹⁵ and equation (3) must be modified.

A further complication is the presence of local magnetic field gradients, which result from the magnetic susceptibility contrast between grain material and pore fluid. Rocks typically have paramagnetic ion contents of about 1%, and grain volumetric susceptibilities (SI dimensionless) are typically $\chi_g = +10^{-4}$; grain susceptibilities of the magnetic minerals are much higher. Pore fluids are usually diamagnetic. The internal gradient is proportional to B_0 . It also depends on the details of the pore geometry, and therefore varies from point to point within the pore space; some realistic models have been developed.^{16,17}

The Carr–Purcell–Meiboom–Gill (CPMG) method mitigates the effect of diffusion in a magnetic field gradient. Keeping both the CPMG echo spacing and the applied magnetic field to a minimum reduces the contribution of diffusion to T_2 relaxation. At low values of B_0 typical of borehole logging tools, in the absence of an applied field gradient, and for closely spaced pulses in the CPMG measurement sequence, T_2 is dominated by surface relaxation. Diffusion effects become

important when substantial field gradients are applied, and/or longer pulse spacings are used.

2.4 Bulk Fluid Processes

The last relaxation process is that of the bulk fluid itself. This occurs in the absence of grain surfaces and internal field gradients, and is unaffected by them. Bulk relaxation often can be neglected, but it is important when fluid is in very large pores and therefore is little affected by a surface. Bulk relaxation can also be important for very viscous fluids, such as heavy oils, and also can be the dominant process when the pore fluid has a high concentration of paramagnetic ions. For example, chromium ligandsulfonate is a common additive in drilling fluids; chromium ion that enters the pore fluid from the borehole can dramatically reduce the observed relaxation time.

Fine particulates from the borehole can also enter the pore space. When in suspension they also reduce the fluid relaxation time, by making ‘floating’ solid surface area available for fluid molecules to encounter. However, it has been shown, using a novel NMR imaging technique, that this is not likely to be a problem for NMR logging tools.¹⁸

2.5 Pore Size Distributions and Distributions of Relaxation Times

Rocks tend to have very broad distributions of pore sizes, and therefore magnetization decays of fluids in rocks are nonexponential. In early work,¹⁹ NMR data were analyzed in terms of two- or three-exponential decays. Later, magnetization decays of water in rock were fitted to stretched exponentials,²⁰ which assumes a particular form of pore size distribution. The most general way to analyze relaxation data is with a distribution (spectrum) of relaxation times: a plot of signal intensity versus relaxation time. In the following discussion, we assume that the transverse relaxation is controlled by the surface relaxation mechanism and that relaxation is surface-limited. The magnetization decay in an individual pore is then monoexponential, and does not depend on pore shape but only on the surface-to-volume ratio:

$$M(t) = M_0 \exp\left(-\frac{t}{T_2}\right) = M_0 \exp\left[-\rho_2 \left(\frac{S}{V}\right)_{\text{pore}} t\right] \quad (4)$$

The time evolution of the magnetization of a sample having a distribution of pore sizes can be expressed as a sum of exponential decays:

$$M(t) = \sum_i m_i \exp\left(-\frac{t}{T_{2i}}\right) = \sum_i m_i \exp\left[-\rho_2 \left(\frac{S}{V}\right)_i t\right] \quad (5)$$

where m_i is proportional to the volume of fluid relaxing at the rate $1/T_{2i}$. The sum of the volumes is proportional to the porosity ϕ :

$$M_0 = \sum_i m_i \propto \phi \quad (6)$$

Thus, in this model, there is a direct mapping from the spectrum of pore sizes, or more precisely the spectrum of surface-to-volume ratios, to the spectrum of relaxation times.

Figure 1 Distribution of relaxation times for a sedimentary rock. The spectrum is a plot of fluid volume as a function of relaxation time. Solid curve: rock fully saturated with water. Dashed curve: the same rock after centrifuging. Centrifugation drains the largest pores, and the corresponding part of the relaxation time distribution disappears. Fluid content before and after centrifuging is directly proportional to the area under the respective curve

Implicit in this discussion is the assumption that pores exist as identifiable entities. On the basis of steady state measurements such as hydraulic permeability and electrical conductivity, it is known that the pore space in rocks is well connected. However, pulse NMR is not a steady state measurement. Molecules only sample a limited volume of pore space before they are relaxed.²¹ The radius of the volume sampled is approximately the root mean square distance the molecule diffuses in the NMR relaxation time, $\sqrt{6DT_1}$, the diffusion coefficient, is itself a function of observation time in porous media.¹⁵ If there is significant coupling of pores of different sizes, the relaxation time distributions will be narrowed.²²

A confirmation of the connection between pore size and NMR relaxation time was provided by Straley et al.²³ Rock specimens were fully saturated with water, and the spectrum of longitudinal relaxation times was determined. Then each rock was centrifuged at a number of rotor speeds. At successively higher speeds, water was progressively expelled from the samples as the centrifugal pressure overcame the capillary pressure of successively smaller pore spaces. At each step, the NMR relaxation spectrum was remeasured. At low centrifuge speed, the components with the longest T_1 disappeared from the spectrum, while the short- T_1 components were unaffected, indicating that only the largest pores had drained. As the centrifuge speed was increased, smaller pores drained and shorter components disappeared. A typical result of a similar T_2 measurement is shown in Figure 1.

The extraction of the values of m_i from the measurement data $M(t)$ poses significant mathematical problems. The inversion is not unique when $M(t)$ is noisy or when the mathematical computation has finite precision. In the past, either the number of terms in equation (5) was limited to two or three—a sparse spectrum indeed—or many terms were used, resulting in spiky, unphysical spectra. This problem can be solved by the use of regularization.²⁴ Regularization has the effect of smoothing the spectrum, which removes spikes and

makes the inversions reproducible. The obvious disadvantages are that the distributions are artificially broadened and that real, narrow features can be filtered out of the results. To avoid problems of arbitrary smoothing, it is essential to use an algorithm that selects the regularization parameter in a data-dependent but objective manner. One such algorithm is that of Butler, Reeds, and Dawson.²⁵ This automatically selects a regularization parameter based on the signal-to-noise ratio of the measurement data to obtain a minimally broadened, but reproducible, inversion.

2.6 Determination of Surface Relaxivity

To relate quantitatively the NMR relaxation rate spectrum to the pore size spectrum, it is necessary to know the coefficient ρ in equations (1) and (2). Determination of the strength of the surface relaxation has proved to be elusive, because it is difficult to obtain independent information on pore size distributions of sedimentary rock.

The first problem is that the connection between a surface-to-volume distribution and a pore size distribution is poorly defined for rocks. The pore space of rocks has been modeled as spheres connected by throats, an interconnected network of tubes, and an interconnected network of sheets. None of these models has universal applicability. Thus the term ‘pore size’ should be understood to mean a quantity inversely proportional to the surface-to-volume ratio of a locality in the pore space.

Even more importantly, grain surfaces can have fractal character.²⁶ That is, the apparent surface area depends on the characteristic scale length η of the measurement. Relaxation time measurements also have characteristic scale lengths: the distance a molecule can diffuse in the shortest recovery time of an inversion-recovery measurement of T_1 , or before the first spin echo of a CPMG determination of T_2 .

Surface area determinations based on low-temperature adsorption of gas, e.g., the BET method,²⁷ probe the surface at molecular scale and are dominated by the finest features of grain surfaces. Optical microscopy of thin sections has a resolution of about $\eta = 5 \mu\text{m}$: large pores appear to have smooth surfaces and small pores are invisible. It is not unusual to find that the surface-to-volume ratio determined by a combination of BET and buoyancy porosity methods is orders of magnitude larger than that determined by optical imaging measurements. An interesting new technique measures the surface-to-volume ratio by pulsed field gradient NMR measurements of diffusion.²⁸ The scale length is determined by the distance fluid molecules diffuse during the finite-length gradient pulses that tag the spins; in recent experiments,²⁹ $\eta = 2 \mu\text{m}$.

The ambiguity in the determination of surface-to-volume ratio results in an ambiguity in the determination of ρ_1 and ρ_2 . When the BET method is used to measure surface area and the relaxation time is determined by the initial slope method, for which $\eta < 1 \mu\text{m}$,²¹ ρ_1 is found to be in the range $0.1\text{--}0.8 \mu\text{m s}^{-1}$. The pulsed field gradient diffusion measurements²⁹ yield ρ_1 in the range $3\text{--}40 \mu\text{m s}^{-1}$. From optical imaging,³⁰ ρ_1 is $30\text{--}300 \mu\text{m s}^{-1}$.

Yet another technique for determining ρ is based on capillary pressure measurements.^{27,31} Differential mercury intrusion porosimetry measures a pore size distribution, on the assumption that the pore space is composed of a well-connected network of tubes of various diameters. For many

sandstones, the pore size distribution deduced from mercury porosimetry overlays the NMR relaxation time distribution.³² These comparisons indicate that $\rho_1 = 4 \mu\text{m s}^{-1}$ and $\rho_2 = 7 \mu\text{m s}^{-1}$.

The relatively high values of ρ_1 found using the optical microscopy, PFG NMR, and capillary pressure methods reflect the fact that they measure not $(S/V)_{\text{pore}}$ but pore size, from which are calculated *effective* relaxivities. Sandstones can have significant amounts of clay or microporosity, which have large surface areas. BET measurements include this surface area while other methods miss it. Since large pore spaces are the dominant passages for fluid flow, the effective relaxivity ρ_{eff} is the appropriate quantity to use to convert relaxation times to pore sizes for many petrophysical applications.

3 PRACTICAL IMPORTANCE OF NMR MEASUREMENTS

3.1 T_1 versus T_2

Relaxation measurements can provide valuable information about rock formations. Unfortunately, measurements of T_1 and T_2 both have serious problems, though the problems are of very different natures. T_2 of fluids in rocks is dominated by molecular diffusion in random internal magnetic field gradients when the Larmor frequency is 10 MHz and above. This makes 'high-field' T_2 difficult to interpret. In contrast, T_1 is generally controlled by the surface relaxation mechanism, because it is unaffected by diffusion in gradients; thus interpretation of T_1 measurements is usually straightforward. However, determination of the longitudinal decay curve requires a time-consuming series of inversion–recovery measurements. For practical reasons, the time available for NMR measurements in an oil well is very limited (see Section 4.1). A CPMG determination of T_2 is much faster, and is therefore preferred.

Fortuitously, the borehole tools are not able to generate high static magnetic fields, and therefore do not generate large internal magnetic field gradients. Static field gradients are either known apparatus constants or are negligible (see Section 4). Under these conditions, transverse relaxation times are readily interpretable. Therefore, most recent work related to borehole NMR has focused on T_2 at frequencies of 2 MHz and below.

3.2 Porosity

Porosity, defined as the fraction of rock volume that can be occupied by fluid, is one of the most important parameters characterizing a hydrocarbon reservoir. In economically significant reservoirs, porosities generally range from 5% to 30%. There are many ways of measuring porosity in situ.^{1,2} The speed of compressional sound waves, the scattering of neutrons, and the scattering of gamma rays are commonly measured for this purpose. However, these techniques require knowledge of the mineralogy of the solid matrix to make a determination of porosity.

NMR has the unique capability of measuring fluid-filled porosity without the need to know anything about the solid matrix. The amplitude of a proton NMR measurement is

directly proportional to the amount of hydrogen in the material investigated. Protons are present in both oil and water (in approximately equal concentrations), in water associated with clay minerals, and in some matrix minerals such as gypsum (calcium sulfate hydrate). T_2 is sufficiently short in solid matrix materials, on the order of $10 \mu\text{s}$, that the signal from protons in the matrix is lost in the deadtime of the borehole instruments. Protons in clay-bound water relax in a millisecond or less, so these generally are lost in the noise of the first one or two CPMG echoes of the borehole tools. On the other hand, relaxation times of protons in the fluids are usually greater than 10 ms, so these protons contribute significantly to the long echo trains collected by the downhole apparatus.

Pore fluids can be further subdivided into capillary-bound fluid and producible fluid. The partition depends on the pressure difference that drives fluids from the rock formation to the wellbore. This pressure is commonly around 0.7 MPa. It has been found that centrifuging sandstones at a differential pressure of 0.7 MPa depletes them of all water protons with $T_1 > 50 \text{ ms}$.²³ Thus protons with $T_1 > 50 \text{ ms}$ (or $T_2 > 30 \text{ ms}$) are associated with large pores containing 'unbound' or 'free' fluid. Although the total porosity measurement is independent of rock type, the 50 ms partition between bound and free fluid is merely typical, and depends on the surface relaxivity (see Section 2.2). Nonetheless, the estimation of producible fluid is a unique and valuable capability of NMR logging tools.

3.3 Permeability to Fluid Flow

Hydraulic permeability is one of the most difficult rock properties to estimate, because it depends sensitively on pore sizes and connectivities, which are themselves hard to measure. In simple models of porous media, the permeability is inversely proportional to the square of the surface-to-volume ratio and therefore directly proportional to the square of the NMR relaxation times, a hypothesis that has been substantiated by a large body of laboratory experiments on water-saturated sandstones.^{20,33} The correlation between hydraulic permeability and NMR relaxation time appears to depend on limited variability of the surface relaxivity. Attempts to establish similar correlations for carbonates have been less successful, probably because their microgeometry is much more diverse than that of sandstones.

3.4 Measurement of Oil Content

Oil and water are generally found together in reservoir rocks. Many factors affect the NMR response of oil and water mixed in porous media:

1. the relative amounts of each phase;
2. the wettability of the grain surfaces;
3. the surface relaxivity;
4. the bulk relaxation times of each phase;
5. the extent to which the original formation fluids have been replaced by borehole fluid filtrate.

When magnetic field gradients are present (see Section 4.5), the restricted diffusion coefficients of the phases are also a factor.

The water–oil interface does not assist relaxation, so if a fluid is not in contact with grain surface, it relaxes at its

bulk liquid relaxation rate. The bulk relaxation time of oil depends on its viscosity, while the bulk relaxation time of water depends primarily on the concentration of paramagnetic ions. The proton density of an oil is generally within 10% of that of water, so its contribution to the relaxation time distribution is simply weighted by concentration.

Most reservoir rocks are thought to be hydrophilic. In such cases, droplets of oil sit in the center of pores and are unaffected by the surface. Therefore they relax at their bulk liquid relaxation time, which can be rather long if the oil has a low viscosity. In many cases, the water in contact with the grains will relax considerably faster, and there can be two distinct peaks in the relaxation time spectrum.²³ Then the amount of oil in the rock can be determined quantitatively.

When the oil is very viscous, its bulk relaxation time is shorter than the tool deadtime, and it will not be detected. Then the NMR porosity is just the water-filled porosity.³⁴ By subtracting the NMR porosity from a porosity measurement that is insensitive to the material properties of the oil, the quantity of oil can be obtained.

Borehole NMR measurements probe the formation to depths of 10 cm or less. In many cases, original formation fluids are flushed away from the rock near the well bore and replaced by borehole fluids ('invasion' by 'mud filtrate'). In these cases, NMR does not give information about the quantity of original oil in place. It can, however, estimate the amount of oil that will be retained in the formation after the usual recovery processes: water floods that, in fact, resemble invasion by mud filtrate, but on a larger scale. This information is useful in planning enhanced oil recovery projects.

4 INSTRUMENTATION FOR WELL LOGGING

4.1 The Borehole Environment and Field Operations

The borehole environment is unusually harsh. Boreholes drilled to extract oil are typically 20 cm in diameter and 1–10 km deep. The geothermal gradient of the Earth can give rise to temperatures of 175 °C or more, and pressures range to 140 MPa. Borehole logging tools must not only survive but must make quantitative measurements under these conditions. The requirements on electronic components exceed military specifications by a wide margin.

Borehole NMR tools must be rugged enough to survive transport in arctic, tropical, desert, and marine environments, and then a 1 m drop onto a steel surface, which typically produces a shock of 500g. They must survive the abrasion resulting from being dragged over kilometers of rough rock face in the well bore. They must comply with laws regulating transport by aircraft and helicopter, which is of particular significance for NMR equipment containing strong permanent magnets. The conditions and space constraints are in many respects more severe than those encountered in the exploration of outer space or the ocean bottom.

During well logging operations, the drilling rig is idle. Since rig charges can be \$10 000 to \$100 000 per day, oil companies wish to minimize logging time. This poses a significant constraint on practical logging operations. Typically, data might be required over a depth interval of 300 m or more, with a vertical resolution of 50 cm. To be economically viable, the NMR apparatus must move continuously past the formation at

a rate of 300 m h⁻¹. This means that it is necessary to measure signal amplitude and a distribution of relaxation times in 6 s, while the sample and apparatus are in motion relative to each other, at low field, and with an unprecedentedly small coil filling factor.

Skilled NMR specialists are not available for logging operations. The borehole NMR tool must be maintained, set up, and operated by field engineers, who also are responsible for other electromagnetic, acoustic, and nuclear radiation instruments that are being run simultaneously. Thus there is a large premium on instruments that can operate autonomously under conditions of continuously changing environmental conditions, including radical excursions in temperature. The NMR and electromagnetic properties of the materials presented to the apparatus also vary radically, on a timescale of seconds.

Logging tools are generally transported to the wellsite on a truck, which also carries 10 km of 7-conductor armored cable ('wireline') used to lower a string of several tools into the borehole. In present practice, the cable carries nothing but 1 kW of power and 500 kilobits s⁻¹ of digital telemetry. The power budget for an individual tool is normally around 100 W, which for an NMR tool must be apportioned among transmitter, receiver, auxiliary sensors, and a downhole computer.

Laboratory NMR apparatus consists of a magnet that provides a strong, steady magnetic field that is as uniform as possible, and a radiofrequency coil that produces an oscillating magnetic field perpendicular to the static field direction. A relatively small, compact sample (which may be a human being) is placed inside the coil. It requires a leap of imagination to see how NMR measurements can be made 'inside-out' on a sample external to the apparatus.

4.2 Early Work

It was recognized at an early date that nuclear magnetic resonance could contribute to the in situ investigation of earth formations. Laboratory NMR studies of fluids in rocks, of clays, and in other porous media started in the 1950s at a number of oil company research laboratories, most notably those of Chevron and Mobil. More than three dozen patent applications for borehole NMR devices were filed between 1950 and 1960, representing work sponsored by Chevron, Schlumberger, Mobil, Texaco, and Varian. Efforts accelerated in the 1960s and 1970s. A chronological bibliography³ is an excellent guide to the early patents and publications.

4.3 Chevron Tool

The first practical NMR borehole logging device did not use magnets and an rf coil, but instead employed free precession in the Earth's magnetic field. It was invented at the Chevron research laboratory,³⁵ and was subsequently commercialized by Schlumberger as the Nuclear Magnetism Tool (NMT). The NMT contains a large coil of 1000 turns of wire energized by 1 kW direct current; the power consumption prevents other tools from being used at the same time as the NMT. The current produces a spatially inhomogeneous magnetic field in the formation. The current is left on for several seconds, long enough to polarize the proton spins of the formation fluids. The

magnetization varies in magnitude and direction from point to point in the earth formation, but over a large volume the polarization is substantially greater than that associated with the Earth's field alone.

The coil current is then turned off rapidly, and the spins precess around the Earth's field direction.³⁶ A signal is coupled into the same coil used to polarize the spins. A bandpass filter selects the signal from hydrogen, which in any event is by far the largest signal of nuclear origin. The proton Larmor frequency in the Earth's magnetic field varies considerably with geographical location: 2.6 kHz in Canada and 1.0 kHz in Argentina. The free induction decay is often controlled by the T_2 of the rock. It can also be affected by small perturbations in the local Earth's field, such as might be caused by grains of magnetic minerals in the formation.

The deadtime of the NMT, controlled by the decay of coil current after the polarizing pulse, is about 25 ms. Most of the signal from clay-bound and capillary-bound fluid has decayed by then, so the amplitude of the remaining signal, extrapolated back to the turn-off time, is directly proportional to the producible fluid porosity ('free fluid index'). The formation response is spatially weighted and decreases rapidly with distance from the coil. Therefore the tool is calibrated in a large tank of water-saturated sand, representing a uniform formation of known porosity.

The borehole is always full of water or oil. In the absence of precautions, the received signal would be dominated by protons in the borehole, which are both closer and more numerous than those in the surrounding rock formation. To solve this problem, the borehole is 'doped' with magnetite (Fe_3O_4) grains. The magnetic grains rapidly relax protons in the wellbore. Since the grains cannot enter the formation, relaxation of protons in the pore fluid is unaffected.

The tool can make neither continuous wave nor pulsed NMR measurements. Neither T_2^* nor T_2 is measured with this device. T_1 can be measured by varying the polarization time, and measuring the signal amplitude at subsequent field turn-offs.

4.4 Los Alamos Tool

An 'inside-out NMR' device was designed and built at Los Alamos National Laboratory (LANL);³⁷ the basic idea is illustrated in Figure 2. The apparatus contains two axially magnetized cylindrical bar magnets. These are placed with like poles facing each other in a cylindrical housing ('sonde'). The radial magnetic field in the transverse symmetry plane is a maximum at a distance from the sonde axis that depends on the radius and spacing of the magnets. A toroidal region of relatively uniform static magnetic field strength is created. A prototype instrument generated a static field of 12 mT in a toroid having a major diameter of 28 cm.

A radiofrequency coil is placed between the magnets, and irradiates the resonance region. In the resonance region, the rf field is perpendicular to the static magnetic field. When driven by 1 kW peak power, the coil generates an oscillating magnetic field of 0.1 mT in the resonance region. The same coil detects the NMR response of the earth formation.

Unlike the field turn-off scheme of the NMT, the LANL tool is capable of performing a variety of pulsed NMR measurements. Both inversion–recovery and Carr–Purcell–

Figure 2 Schematic views of Los Alamos NMR well logging tool. (a) Static field generation. (b) rf field generation. The inset shows a cross section of the toroidal resonance region, where B_0 is perpendicular to B_1 . (Reproduced by permission of Academic Press from J. A. Jackson et al., *J. Magn. Reson.*, 1980, **41**, 411)

Meiboom–Gill measurements are easy to implement. Pulse lengths are comparable to those of laboratory instruments, and the 200 μs deadtime achieved at Los Alamos is adequate for relaxation measurements on rock formations.

Although the Los Alamos design was never commercialized, it attracted considerable interest in the geophysical community, and was an inspiration for a number of other tool design efforts.

4.5 NUMAR Tool

Shtrickman and Taicher invented another NMR borehole logging tool,³⁸ and a small company (NUMAR) commercialized the technology. A cylindrical ferrite magnet roughly 1 m long is magnetized perpendicular to its long axis. A cross-sectional view is shown in Figure 3. The field outside the magnet is purely dipolar in the transverse plane; thus the magnitude of B_0 is independent of azimuth and depends only on radius.

The radiofrequency field B_1 is provided by a coil wound longitudinally around the magnet, so that B_1 is also transverse to the tool's long axis. Whereas a metallic magnet would

Figure 3 Cross-sectional view of the NUMAR tool. The permanent magnet is magnetized in the direction of the arrow. The tool is centered in the borehole, and the resonance region is a thin cylindrical shell. B_0 is perpendicular to B_1 everywhere in space. (Courtesy of NUMAR Corp.)

exclude the rf field from its interior, the ferrite magnet allows free penetration of the field, improving efficiency in both transmission and reception. The windings are spaced so as to produce a dipolar field, and so, like B_0 , the magnitude of B_1 is independent of azimuth. Because the dipoles are perpendicular to each other, B_1 is perpendicular to B_0 at every point in space.

The NUMAR tool is unusual in that it does not produce a region of uniform static magnetic field; to be more precise, there is no place outside the magnet where all spatial derivatives of B_0 vanish. The coil may be energized at any frequency: selecting a frequency selects a thin cylindrical shell on which the resonance condition is satisfied. The cylindrical resonant shell has thickness because spin tipping is effective where $B_1 > |B_0(r) - B_0(r_0)|$, where $B_0(r)$ is the static magnetic field at radius r , and r_0 is the radius at which the resonance condition is exactly satisfied. Thus, the larger the B_1 , the thicker the shell from which signal is obtained. The resonance frequency is selected to be between 0.5 and 1 MHz, with resonant shell radii $r_0 = 0.23$ and 0.18 m, respectively. $dB_0(r_0)/dr = 0.25 \text{ T m}^{-1}$, and the shell is 2.5 mm thick. Volume selection allows CPMG sequences to be collected continuously without waiting for longitudinal recovery: the tool hops between two or more frequencies, resonating separate shells during successive sequences.

The applied gradient of 0.25 T m^{-1} is considerably larger than typical internal gradients due to magnetic susceptibility contrast between grains and pore fluids of rocks. Diffusion in the magnetic field gradient is an important contribution to transverse relaxation, and must be taken into account explicitly in understanding the measurements. Since the magnetic field gradient is known, an effective diffusion coefficient can be estimated by varying the CPMG pulse spacing. Extrapolating

Figure 4 Cross-sectional view of the Schlumberger tool. The permanent magnets are magnetized in the direction of the arrows. The sonde is pressed against the borehole wall, and B_0 is directed radially into the formation. A region of relatively homogeneous magnetic field is located inside the formation. Colors code for static field strengths: the resonance region is coded in yellow, stronger fields are coded in greens, weaker fields in reds. The antenna is in a semicircular cavity under a nonmetallic wear plate

the pulse spacing to zero allows estimation of the part of T_2 that is due to surface relaxation.

4.6 Schlumberger Tool

Schlumberger has developed a novel tool design for NMR logging.³⁹ Unlike the other tools, the sonde is pressed against the borehole wall; the length of the wall-engaging section is about 40 cm. A cross sectional view of the Schlumberger logging sonde is shown in Figure 4. Two samarium cobalt magnets are magnetized in the same direction, transverse to the sonde axis. The static magnetic field is predominantly radial into the formation. The figure shows a contour plot of the total field strength in the plane transverse to the borehole axis. The field has a saddle point about 25 mm inside the formation; at this location, all three spatial derivatives of B_0 are zero. The field strength in the resonant region is 55 mT, so the Larmor frequency is 2.3 MHz.

The antenna used to radiate the formation at the resonance frequency is placed in a semicircular cylindrical cavity on the face of the sonde. The antenna is essentially a half coaxial cable 15 cm long that irradiates the formation with a field transverse to the static field. It is loaded with ferrite and has a high Q , which is desirable for the reception of weak signals from the nuclear spin system. The field produced by the antenna is not particularly homogeneous over the resonance region; inhomogeneity of B_1 is acceptable, so long as error-correcting pulse sequences such as the Carr–Purcell–Meiboom–Gill sequence are used. The antenna resides underneath a wear plate, which is the only nonmetallic surface on an otherwise all-metal sonde. Magnetoacoustic ringing of metal structures, which would increase the deadtime of the instrument, is suppressed.

Figure 5 NMR well log. Left panel: A log of the transverse relaxation time distribution is shown in blue, darker color indicating higher amplitude. The red line is the logarithmic mean of T_2 . Right panel: The variegated orange and brown background is an unwrapped electrical image of the borehole wall, showing fine stratigraphic features. NMR porosity is shown as a black curve, producible fluid porosity is shown as a green curve, and permeability to fluid flow is shown as a blue curve. The curves are explained fully in the text. The depth scale is in feet; the most significant figure has been replaced by X (Reproduced by courtesy of Schlumberger)

4.7 Log Example

A well log consists of the readings of one or more borehole logging tools plotted as a function of depth. Figure 5 is an example of an NMR well log. The vertical scale is depth, marked in feet. The left panel is a presentation of the spectrum of transverse relaxation times; the horizontal scale is T_2 in milliseconds. Higher amplitude is coded as darker color. This is an indicator of pore size distribution: for example, high amplitude at short relaxation times indicates a formation with relatively small pores. The red line is the logarithmic mean of T_2 , T_{2LM} :

$$T_{2LM} = \exp(\log T_2) = \exp\left(\frac{\sum_i m_i \log T_{2i}}{\sum_i m_i}\right) \quad (7)$$

On the right panel is an electrical image of the borehole created by the Formation Microscanner (FMS). The FMS measures the local electrical conductivity using a number of small electrodes placed in contact with the borehole wall by retracting arms. Darker colors indicate high electrical conductivity, usually associated with the presence of saline water or clay. Lighter colors indicate low conductivity, and suggest low porosity or the presence of oil. The resulting electrical image of the borehole is unwrapped: the 0° azimuth is at the left edge of the panel and the 360° azimuth is at the right. The blank stripes represent areas of the borehole wall that are not in contact with the four arms of the tool. The stripes change azimuth slowly because the tool rotates as it is pulled up.

The NMR logs overlay the FMS image. By convention, porosity is plotted on the right-hand side of the panel and increases to the left, while hydraulic permeability is plotted on the left-hand side of the panel and increases to the right. The total NMR porosity is shown in black and the producible fraction of the porosity in green. Zones with small pores have low producible porosity, even when the total porosity is high. The permeability to fluid flow (measured in millidarcies, mD) is computed using the empirical equation

$$k = (2.25 \times 10^6 \text{ mD s}^{-2}) \phi^4 T_{2LM}^2 \quad (8)$$

where ϕ is the porosity. The permeability is plotted on a logarithmic scale, and changes by orders of magnitude from one zone to the next. In this powerful combination of measurements, the FMS gives a high-resolution stratigraphic image of the subsurface, while NMR provides quantitative producibility information.

1 INTRODUCTION

Conventional methods of crystal structure determination such as X-ray and neutron scattering yield the unit cell structure averaged over space and time. While the knowledge of such a space and time averaged structure is sufficient in most systems this is not the case in inhomogeneous- or order-disorder-type ferroelectrics and proton glasses where local deviations from the averaged structure determine the specific properties of these systems. 1D and 2D NMR of nuclei with a nonzero quadrupole coupling or chemical shift tensor interaction as well as NQR provide here a unique tool for the determination of the local atomic structure and dynamics which is unobtainable by other techniques.

In the fast motion regime, $\omega\tau \ll 1$, the nucleus at site i ‘sees’ the time averaged value of the quadrupole coupling or chemical shift tensor interaction so that¹

$$\omega_i = \omega_0 + \omega_1 \langle \eta_i \rangle; \quad \langle \eta_i \rangle \neq 0 \quad T < T_c \quad (1a)$$

whereas

$$\omega_i = \omega_0; \quad \langle \eta_i \rangle = 0 \quad T > T_c \quad (1b)$$

Here $\langle \eta_i \rangle$ is the time averaged value of the long-range order parameter at site i . It is $\langle \eta_i \rangle$ which is zero above T_c and non-zero below T_c .

Close to the phase transition temperature T_c , the spin-lattice relaxation rate will be determined by the order parameter fluctuations¹

$$T_1^{-1} \propto \sum_{\mathbf{q}} \int_{-\infty}^{\infty} \langle \delta \eta(\mathbf{q}, 0) \delta \eta(\mathbf{q}, t) \rangle e^{i\omega t} dt \quad (2a)$$

where $\delta \eta(\mathbf{q}, t) = \eta(\mathbf{q}, t) - \langle \eta(\mathbf{q}, t) \rangle$ and $\langle \dots \rangle$ denotes the ensemble average.

Applying the fluctuation dissipation theorem, equation (3) can be rewritten as¹

$$T_1^{-1} \propto \sum_{\mathbf{q}} \frac{\chi(\mathbf{q}, 0) \tau(\mathbf{q})}{1 + \omega^2 \tau(\mathbf{q})^2} \quad (2b)$$

where $\chi(\mathbf{q}, 0)$ is the wave vector dependent static susceptibility of the order parameter and $\tau(\mathbf{q})$ is the corresponding wave vector dependent correlation time.¹ For the Ising model one finds

$$\chi(\mathbf{q}) = \frac{\chi(\mathbf{q} = 0, 0)}{1 + \mathbf{q}^2 \xi^2} \quad (3a)$$

and

$$\tau(\mathbf{q}) = \frac{\tau(\mathbf{q} = 0)}{1 + \mathbf{q}^2 \xi^2} \quad (3b)$$

where

$$\tau(\mathbf{q} = 0) \propto \chi(\mathbf{q} = 0) \propto \frac{C}{T - T_c}; \quad T > T_c \quad (3c)$$

and ξ is the correlation length, which diverges at T_c . In the limit $\omega\tau \ll 1$ T_1^{-1} thus exhibits a critical behavior near T_c , while for $\omega\tau \gg 1$ T_1^{-1} should stay nearly constant. Another point to be stressed is that in the slow motion regime the nucleus ‘sees’ the instantaneous value of the order parameter and not the time averaged value.

2 INHOMOGENEOUS FERROELECTRICS AND PROTON GLASSES

Ferroelectric and antiferroelectric phase transitions¹ are characterized by:

1. the breaking of a discrete symmetry group at the paraelectric to ferroelectric or antiferroelectric transition;
2. the appearance of a long-range order parameter below T_c —the spontaneous polarization P in ferroelectrics or the sublattice polarization $P_a = -P_b$ in antiferroelectrics;
3. the critical slowing down of the order parameter dynamics $\tau(\mathbf{q}_{\text{crit}}) \rightarrow \infty$ as $T \rightarrow T_c$ from above or below.

The breaking of the symmetry of the high temperature paraelectric phase is the result of the condensation of a polar soft phonon or a—usually overdamped—soft pseudospin wave mode, the frequency of which increases with decreasing temperature in the high-temperature phase and vanishes at T_c . The frozen out eigenvector of the soft mode represents the order parameter of the transition. In ferroelectrics the condensation of the soft mode occurs at the Brillouin zone center, whereas it occurs in antiferroelectrics at the Brillouin zone boundary.

The free energy of a ferroelectric with a one-component order parameter has a single minimum at $P = 0$ at $T > T_c$ and two minima at $+P$ and $-P$ below T_c corresponding to oppositely polarized domains [Figure 1(a)].

Solid solutions of ferroelectric (FE) and antiferroelectric (AFE) crystals form in the intermediate concentration range $x_{\text{FE}} \leq x \leq x_{\text{AFE}}$ (Figure 2) a pseudospin-like dipolar glassy phase where no macroscopic symmetry breaking takes place

Figure 1 Free energy surface in (a) a homogeneous ferroelectric and (b) a deuteron pseudospin glass

at any temperature and no long range order parameter appears. Instead we have a random local freeze-out of the dipoles and possibly an ergodic–nonergodic transition. The existence of the glassy phase is due to randomly competing ferroelectric and antiferroelectric interactions and the resulting random frustration of the system. The free energy surface of such a system is rough and fractal-like and exhibits a large number of nearly degenerate minima separated by high potential barriers² [Figure 1(b)]

In the concentration range $0 \leq x \leq x_{\text{FE}}$ and $x_{\text{AFE}} \leq x \leq 1$ (Figure 2) we have an inhomogeneous ferroelectric and antiferroelectric phase, respectively, where long range order and glassy order coexist at $T \neq 0$.

Figure 2 Phase diagram⁵ of the ferroelectric solid solution $\text{Rb}_{1-x}(\text{ND}_4)_x \text{D}_2\text{PO}_4$ which forms a deuteron glass in the intermediate concentration range $x_{\text{FE}} \leq x \leq x_{\text{AFE}}$. Also shown are the inhomogeneous ferroelectric and inhomogeneous antiferroelectric regions for $0 \leq x \leq x_{\text{FE}}$ and $x_{\text{AFE}} \leq x \leq 1$. The solid lines are calculated from the random bond–random field pseudospin Ising model. Also shown is the Almeida–Thouless (AT) line separating the ergodic from the nonergodic glassy phase

The local dipolar structure of the above phases can be characterized by a local polarization distribution function,³

$$W(p) = \frac{1}{N} \sum_i \delta(p - \langle S_i^z \rangle) \quad (4)$$

where the pseudospin $S_i^z = \pm 1$ describes the two orientational states of the dipole at site i , and the brackets $\langle \dots \rangle$ stand for the thermal average. In a homogeneous ferroelectric the first moment of $W(p)$,

$$P = \int W(p) p \, dp \neq 0 \quad T < T_c \quad (5a)$$

$$P = 0 \quad T > T_c \quad (5b)$$

is the spontaneous polarization

$$P = \frac{1}{N} \sum_i \langle S_i^z \rangle \quad (5c)$$

which is different from zero for $T < T_c$ and zero for $T > T_c$.

In a homogeneous ferroelectric

$$W(p) = \delta(p - P) \quad (5d)$$

and the second moment of $W(p)$ is zero,

$$\tilde{q} = q - P^2 = \int W(p) p^2 \, dp - P^2 = 0 \quad (5e)$$

In a proton or deuteron dipolar glass the first moment of $W(p)$ is zero as there is no long range order,

$$P = \int W(p) p \, dp = 0 \quad (6a)$$

but the second moment of $W(p)$ is different from zero,

$$q = \int W(p) p^2 \, dp \neq 0 \quad (6b)$$

Here, q is just the well known Edwards–Anderson glass order parameter which is also defined² as

$$q = \lim_{t \rightarrow \infty} \lim_{N \rightarrow \infty} \frac{1}{N} \sum_i \langle S_i^z(0) S_i^z(t) \rangle \quad (6c)$$

If there are no random fields present, we have a paraelectric–glass transition³ at T_g :

$$q = 0 \quad T > T_g \quad (7a)$$

$$q \neq 0 \quad T < T_g \quad (7b)$$

In the presence of a random field, which is conjugate to this glass order parameter, $q \neq 0$ at all temperatures.^{3,4} We have, however, at lower temperatures an ergodic–nonergodic transition below the Almeida–Thouless line in the random field variance–temperature plane where the pseudospin glass susceptibility, as well as the longest glass relaxation time,

diverge.^{2,5} Here the replica symmetry of the ‘ergodic’ glassy phase is broken² and instead of a single order parameter q we have an infinite number of order parameters represented by the order parameter function² $q(x)$.

In an inhomogeneous ferroelectric, on the other hand, both

$$P \neq 0 \quad (8a)$$

and

$$\tilde{q} = q - P^2 \neq 0 \quad (8b)$$

The local polarization distribution function $W(p)$ is reflected in the inhomogeneous NMR frequency spectrum $f(\omega)$ via

$$f(\omega) d\omega = W(p) dp \quad (9)$$

A knowledge of the inhomogeneous NMR frequency spectrum $f(\omega)$, obtainable by 2D ‘separation of interactions’ NMR, and the relationship $\omega = \omega(p)$ thus enables one to determine $W(p)$ and all its moments. This is of crucial importance in glasses and inhomogeneous ferroelectrics and antiferroelectrics.

3 NMR IN HOMOGENEOUS FERROELECTRICS AND ANTIFERROELECTRICS IN THE FAST MOTION REGIME

3.1 Deuteron NMR and Relaxation

In hydrogen-bonded ferroelectrics and antiferroelectrics the O–H···O bonds are of the double-well type (Figure 3) and are the main reversible dipoles in the structure. The two positions of the proton ($I = \frac{1}{2}$) or respectively deuteron ($I = 1$) in this limit can be represented by a pseudospin $S^z = \pm 1$. The quadrupole perturbed NMR frequency of the deuteron ω_i changes when the deuteron is transferred from the ‘left’ to the ‘right’ position, O–H···O $\leftrightarrow$ O···H–O, in the double-well potential:

$$\omega_i = \omega_0 + \omega_1 S_i^z(t) \quad (10a)$$

Figure 3 Double-well O–H···O hydrogen bond potential in hydrogen-bonded ferroelectrics. The two positions of the proton or deuteron in this potential can be described by a pseudospin $S^z = \pm 1$

Figure 4 Time dependence of the pseudospin variable $S^z(t)$ reflecting the deuteron motion between the two equilibrium sites in the O–H···O bond

In the ‘fast motion’ limit, where $\tau \ll \tau_{\text{NMR}} = 1/2\omega_1$ (Figure 4) the nucleus ‘sees’ just the time averaged value of $S_i^z(t)$ so that equation (10a) becomes

$$\omega_i = \omega_0 + \omega_1 p_i \quad (10b)$$

where $p_i = \langle S_i^z(t) \rangle$ is the local polarization. In a homogeneous ferroelectric, where equation (5d) holds, $p_i = p_j = p = P$, so that ^2H NMR provides a method for a microscopic measurement of the long range order parameter P as well as yielding direct information about the deuteron order–disorder transition at T_c in KD_2PO_4 -type crystals.¹ As it can be seen from Figure 5, $\langle S^z(t) \rangle = 0$ above T_c and $\langle S^z(t) \rangle \neq 0$ below T_c . The deuterons are dynamically disordered between the two equilibrium sites above T_c and order into one of the two positions below T_c .⁶ The T dependence of $p = P$ is equal to the one determined by macroscopic polarization measurements.

The fluctuating part of the local polarization $p_i = p + \delta p_i(t)$ and the related part of the quadrupole coupling Hamiltonian $\hat{\mathcal{H}}_Q^{(1)}(t)$,

$$\hat{\mathcal{H}}_Q(t) = \langle \hat{\mathcal{H}}_Q \rangle + \hat{\mathcal{H}}_Q^{(1)}(t) \quad (11a)$$

produces, in agreement with equations (2) and (3), a characteristic dip in T_1 at T_c (Figure 6). The form of the T_1^{-1} anomaly

Figure 5 Temperature dependence of the quadrupole splitting of the deuteron NMR lines in CsD_2AsO_4

Figure 6 Temperature dependence of the deuteron spin-lattice relaxation rate in KD_2PO_4 at $B_0 = 1.65 \text{ T}$

is the one expected¹ for the condensation of an overdamped soft pseudospin wave mode:

$$T_1^{-1} \propto \ln \frac{T - T_c}{T_c} + \text{constant} \quad T > T_c \quad (11b)$$

$$T_1^{-1} \propto 1 - p^2 \quad T < T_c \quad (11c)$$

From the above data the noninteracting deuteron correlation time, i.e. the time the deuteron stays at a given site before it jumps to the other site in the $\text{O}-\text{D}\cdots\text{O}$ potential, is determined as $\tau_0 = 2.7 \times 10^{-13} \text{ s}$ at room temperature. This justifies the fast motion approximation. Similar results were obtained in other hydrogen bonded ferroelectrics.^{1,7}

3.2 Oxygen-17-Proton Nuclear Quadrupole Double Resonance

In view of the ‘geometrical’ isotope effect⁸ and the resulting expansion and changes in the shape of the hydrogen bond potential on deuteration one cannot simply transfer the conclusions obtained for deuterated crystals to the undeuterated ones. Since the distance between the two equilibrium sites of the hydrogen in short $\text{O}-\text{H}\cdots\text{O}$ bonds ($R_{\text{O}-\text{O}} \leq 2.49 \text{ \AA}$) may be $0.35 \text{ \AA}$ or less, it is difficult to determine by neutron diffraction whether the proton is located in the center of the hydrogen bond or dynamically disordered between two separate, off-center equilibrium sites. For $T > T_c$ a single peaked proton density distribution in the center of the hydrogen bond is usually observed by neutron scattering. Below T_c the diffraction data show an off-center position of the proton.

The answer is provided by $^{17}\text{O}-^1\text{H}$ quadrupole double resonance spectroscopy and the direct determination of the $^{17}\text{O}-^1\text{H}$ distance from the magnetic dipole-dipole fine structure of the ^{17}O NQR lines.⁹

As an example let us consider⁷ RbH_2PO_4 , which is isomorphous with KH_2PO_4 and has all $\text{O}-\text{H}\cdots\text{O}$ bonds equivalent. In this system the PO_4 groups are linked by $\text{O}-\text{H}\cdots\text{O}$ bonds. In view of the low natural abundance of ^{17}O (0.037%) there is at most one ^{17}O nucleus ($I = \frac{5}{2}$) per $\text{O}-\text{H}\cdots\text{O}$ bond.

The energies of the three doubly degenerate ($|\pm \frac{1}{2}\rangle, |\pm \frac{3}{2}\rangle, |\pm \frac{5}{2}\rangle$) ^{17}O quadrupole energy levels $E = x A$, $A = e^2 q Q / 4I(2I - 1)$, $eq = V_{zz}$ can be obtained from

$$x^3 - 7(3 + \eta^2)x - 20(1 - \eta^2) = 0 \quad (12)$$

where $\eta = (V_{xx} - V_{yy})/V_{zz}$ is the asymmetry parameter of the EFG tensor and where $V_{zz} \geq V_{yy} \geq V_{xx}$. For small η we have

$$\nu_{1/2 \rightarrow 3/2} = \frac{3e^2 q Q}{20h} \left(1 + \frac{59}{54} \eta^2 \right) \quad (13a)$$

$$\nu_{1/2 \rightarrow 5/2} = \frac{3e^2 q Q}{10h} \left(1 - \frac{11}{54} \eta^2 \right) \quad (13b)$$

and $\nu_{1/2 \rightarrow 5/2} = \nu_{1/2 \rightarrow 3/2} + \nu_{3/2 \rightarrow 5/2}$.

If the proton is centrally located we expect just one set of ^{17}O NQR lines ($\nu_{1/2 \rightarrow 3/2}, \nu_{3/2 \rightarrow 5/2}, \nu_{1/2 \rightarrow 5/2}$) per $^{17}\text{O}-\text{H}\cdots\text{O}$ bond. If the proton is located in an ‘off-center’ site we expect, in view of the random occurrence of the ^{17}O isotope, two sets of ^{17}O NQR lines per $\text{O}-\text{H}\cdots\text{O}$ bond. One of them would correspond to the proton in the ‘close’ position, i.e. $^{17}\text{O}-\text{H}\cdots\text{O}$, and the other to the proton in the ‘far’ position, i.e. $^{17}\text{O}\cdots\text{H}-\text{O}$. If the protons are dynamically disordered between the two ‘off’-center sites, the observed ^{17}O EFG tensor should be an average of the tensors for the two separate ‘off’-center sites, the ‘far’ and the ‘close’ one. It should be noted that the ^{17}O quadrupole coupling constant increases with decreasing $\text{O}-\text{H}$ bond distance,⁸ thus allowing for a discrimination between ‘close’ and ‘far’ sites.

The ^{17}O nuclear quadrupole double resonance results for RbH_2PO_4 are shown in Figure 7. Above T_c only three ^{17}O lines ($\nu_{1/2 \rightarrow 3/2}, \nu_{3/2 \rightarrow 5/2}, \nu_{1/2 \rightarrow 5/2}$) are observed, demonstrating that all PO_4 oxygen sites are equivalent on the NQR timescale. Below T_c each line splits symmetrically into two components, demonstrating that we are dealing with dynamic disorder between two equivalent sites above T_c . The average value of the two components is constant while the difference is proportional to the order parameter p and measures the time averaged asymmetry in the hydrogen bond potential below T_c . We thus have

$$\begin{aligned} \langle \mathbf{V} (^{17}\text{O}-\text{H}) \rangle &= \langle \mathbf{V} (^{17}\text{O}\cdots\text{H}) \rangle \\ &= \frac{1}{2} [\mathbf{V} (^{17}\text{O}-\text{H}) \\ &\quad + \mathbf{V} (^{17}\text{O}\cdots\text{H})] \quad T > T_c \end{aligned} \quad (14a)$$

Figure 7 Temperature dependence of (a) the ^{17}O NQR transition frequencies in RbH_2PO_4 and (b) the quadrupole coupling constant and asymmetry parameter

and

$$\langle \mathbf{V} (^{17}\text{O}-\text{H}) \rangle = \frac{1+p}{2} \mathbf{V} (^{17}\text{O}-\text{H}) + \frac{1-p}{2} \mathbf{V} (^{17}\text{O} \cdots \text{H}) \quad T < T_c \quad (14b)$$

$$\langle \mathbf{V} (^{17}\text{O} \cdots \text{H}) \rangle = \frac{1-p}{2} \mathbf{V} (^{17}\text{O}-\text{H}) + \frac{1+p}{2} \mathbf{V} (^{17}\text{O} \cdots \text{H}) \quad T < T_c \quad (14c)$$

Figure 8 Field sequence for the ^{17}O -H double resonance in the laboratory frame experiment

The difference

$$\langle \mathbf{V} (^{17}\text{O}-\text{H}) \rangle - \langle \mathbf{V} (^{17}\text{O} \cdots \text{H}) \rangle = p[\mathbf{V} (^{17}\text{O}-\text{H}) \times - \mathbf{V} (^{17}\text{O} \cdots \text{H})] \quad (14d)$$

is here indeed proportional to p and allows for a measurement of the local asymmetry of the hydrogen bond potential in frequency units.

The corresponding measuring sequence for the ^{17}O - ^1H double resonance experiment in the laboratory frame is schematically shown in Figure 8.

An independent confirmation of the above results is provided by the proton magnetic dipolar fine structure of the ^{17}O lines obtained with a double frequency irradiation technique.⁹ For $\eta = 0$, $E_{\pm 5/2}$ and $E_{\pm 3/2}$ split up into two doubly degenerate energy levels,

$$E_{\pm 5/2} = \frac{e^2qQ}{4} \pm \frac{5}{2}K\sqrt{1+3\cos^2\theta} \quad (15a)$$

$$E_{\pm 3/2} = -\frac{e^2qQ}{20} \pm \frac{3}{2}K\sqrt{1+3\cos^2\theta} \quad (15b)$$

whereas $E_{\pm 1/2}$ splits into four levels,

$$E_{\pm 1/2} = -\frac{e^2qQ}{5} + \frac{K}{2}[3 \pm \sqrt{37-12\cos 2\theta}] \quad (15c)$$

$$E_{\pm 1/2} = -\frac{e^2qQ}{5} + \frac{K}{2}[-3 \pm \sqrt{13-12\cos 2\theta}] \quad (15d)$$

Here $K/\hbar = 8.16 \text{ kHz}/R_{\text{O-H}}^3$ (angstroms), $\hbar$ is Planck's constant, and θ is the angle between the largest principal axis of the axially symmetric ($\eta = 0$) ^{17}O EFG tensor and the ^{17}O -H bond direction.

The effective dipolar splitting of the ^{17}O NQR lines is determined by

$$\langle R^{-3} \rangle = \frac{1+p}{2} R_{\text{O-H}}^{-3} + \frac{1-p}{2} R_{\text{O} \cdots \text{H}}^{-3} \quad T < T_c \quad (16a)$$

where p can be determined from the temperature dependence of the ^{17}O lines. The ^{17}O -H distance for the 'close' proton

site is here obtained as $R_{O-H} = 1.06 \pm 0.01 \text{ \AA}$ at $T = 138 \text{ K}$, i.e. well below T_c . The result agrees with the one obtained by neutron scattering.

Above T_c the proton spends an equal amount of time at the ‘close’ ($R_{O-H} = 1.06 \text{ \AA}$) and ‘far’ ($R_{O\cdots H} = 1.45 \text{ \AA}$) equilibrium site so that the dipolar splitting is characterized by an ‘apparent’ $^{17}\text{O-H}$ distance

$$\langle R^{-3} \rangle = \frac{1}{2} [R_{O-H}^{-3} + R_{O\cdots H}^{-3}] \quad T > T_c \quad (16b)$$

yielding $R = 1.18 \text{ \AA}$. If, on the other hand, the proton is above T_c , situated in the center of the O–H–O bond, the effective O–H distance obtained from the dipolar fine structure would be

$$R_{\text{symm}}(\text{O-H}) = 1.225 \text{ \AA} \quad T > T_c \quad (16c)$$

which would contradict the experimental data. The ^{17}O quadrupole coupling as well as the $^{17}\text{O-H}$ magnetic dipolar fine structure thus provide direct evidence for the proton intra- $^{17}\text{O-H} \cdots \text{O} \leftrightarrow ^{17}\text{O} \cdots \text{H-O}$ motion between the two sites and the dynamic order–disorder nature of the phase transition in RbH_2PO_4 .

Similar results were obtained for KH_2PO_4 , CsH_2PO_4 , TiH_2PO_4 , PbHPO_4 , as well as squaric acid ($\text{C}_4\text{H}_2\text{O}_2$) and $\text{KH}_3(\text{SeO}_3)_2$.^{7,10} In partially deuterated $\text{RbH}_{2x}\text{D}_{2(1-x)}\text{PO}_4$ the results show that the O–H $\cdots$ O bonds are practically identical to the ones in pure RbH_2PO_4 whereas the O–D $\cdots$ O bonds expand and show a nearly 25% higher spontaneous asymmetry below T_c than the O–H $\cdots$ O bonds.⁷

3.3 Proton Chemical Shift Tensors

For protons ($I = \frac{1}{2}$) in solids, the chemical shift term $\hat{\mathcal{H}}_\sigma$ in the spin Hamiltonian

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_D + \hat{\mathcal{H}}_\sigma \quad (17a)$$

$$\hat{\mathcal{H}}_\sigma = \gamma \sum_i \hat{\mathbf{I}}_i \cdot \boldsymbol{\sigma}_i \cdot \mathbf{B}_0 \quad (17b)$$

is usually much smaller than the dipolar term so that proton chemical shifts are lost in the dipolar width of the NMR line. Using high-resolution NMR-in-solids techniques like the WAHUA sequence,¹¹

$$(\tau, P_x, 2\tau, P_{-x}, \tau, P_y, 2\tau, P_{-y})$$

the homonuclear dipolar broadening can be eliminated while the chemical shifts are reduced by $\sqrt{3}$. This allows for a determination of the proton chemical shift tensors $\boldsymbol{\sigma}$ from the angular dependence of the spectra. Such measurements were performed in KH_2PO_4 and other hydrogen bonded systems.¹² The information obtained is in principle similar to that obtained from the deuteron quadrupole coupling data but the experiments are more tedious and the resolution is lower.

3.4 Phosphorus-31 Chemical Shift Tensors

Whereas ^{17}O NQR and deuteron quadrupole perturbed NMR measure the single-particle intra-hydrogen bond dynamics, the ^{31}P chemical shift tensor $\boldsymbol{\sigma}$ interaction in KH_2PO_4 -type crystals measures the local arrangement of the four O–H $\cdots$ O bonded protons in the hydrogen bonds linking a given PO_4 group to its neighbors. The chemical shift term is

$$\hat{\mathcal{H}}_\sigma = \gamma \sum_i \hat{\mathbf{I}}_i \cdot \boldsymbol{\sigma}_i \cdot \mathbf{B}_0 \quad (18a)$$

where

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}(p_1, p_2, p_3, p_4) \quad (18b)$$

The temperature dependence of the ^{31}P chemical shift on going through T_c in KD_2PO_4 is shown^{7,10} in Figure 9(a). There are four ^{31}P nuclei per unit cell of KH_2PO_4 both above and below T_c . The edges of two PO_4 tetrahedra are rotated by $+13^\circ$ with respect to the orthorhombic a, b axes (A sites) whereas the other two are rotated by -13° (B sites). Above T_c all ^{31}P sites in the unit cell are chemically and physically equivalent due to dynamic proton disorder in the O–H $\cdots$ O bonds. The ^{31}P chemical shift tensor is axially symmetric around the fourfold c axis which passes through

Figure 9 (a) Temperature dependence of the ^{31}P chemical shift on cooling through T_c in KD_2PO_4 . (b) Splitting of the ^{31}P NMR line¹¹ in pseudo-1D CsD_2PO_4 where the O–H(1) $\cdots$ O bonds are ordered above and below T_c whereas the O–H(2) $\cdots$ O bonds are disordered above T_c and ordered below T_c and where $\sigma_{T>T_c} = \frac{1}{2}(\sigma_1 + \sigma_2)$ and $\sigma_{T<T_c}$

the phosphorus sites. Below T_c there are four physically nonequivalent ^{31}P sites, which are all chemically equivalent and which reflect the ordering of the four protons into two ‘close’ and two ‘far’ sites in the $\text{O}-\text{H}\cdots\text{O}$ bonds: $\sigma_1 = \sigma_A(+\mathbf{P})$, $\sigma_2 = \sigma_A(-\mathbf{P})$, $\sigma_3 = \sigma_B(+\mathbf{P})$, $\sigma_4 = \sigma_B(-\mathbf{P})$. The paraelectric σ tensor is the average of the four ferroelectric ones.^{7,10} This confirms that the phase transition in KH_2PO_4 is a protonic order–disorder one and is not driven by electronic instabilities.

The largest principal axes of the ^{31}P chemical shift tensor is nearly exactly parallel to the line connecting the two PO_4 oxygens to which the protons are directly attached. A change in the H_2PO_4 proton ‘arrangement’ from the ‘top’ to the ‘bottom’ oxygens, as viewed along the c axis, results in a polarization reversal ($\mathbf{P} \rightarrow -\mathbf{P}$) and in a rotation of the two largest principal axes of the ^{31}P σ tensor by 90° . The ^{31}P σ tensor is thus a very sensitive indicator of the arrangement of the four protons around a given PO_4 group in KH_2PO_4 crystals.

Similar results were also obtained in pseudo-1D CsD_2PO_4 ¹³ [Figure 9(b)] and PbHPO_4 ¹⁴ using high-resolution NMR-in-solids techniques.

3.5 Arsenic-75 Quadrupolar Coupling

Information similar to that from the ^{31}P chemical shift tensor can be obtained from the ^{75}As quadrupole coupling tensor in KH_2AsO_4 -type arsenates.

Here, however, the resolution of the experiment is much larger as the ^{75}As NQR frequency changes¹⁰ from ≈ 3.5 MHz at $T > T_c$ to ≈ 35 MHz at $T < T_c$ (Figure 10). The ^{75}As EFG tensor as well depends on the arrangement of the four protons around a given AsO_4 group:

$$\mathbf{V} = \mathbf{V}(p_1, p_2, p_3, p_4) \quad (19)$$

The direction of the largest principal axis (V_{zz}) of this tensor is parallel to the line connecting the two oxygens in the AsO_4 group to which the two protons are directly attached, whereas the smallest principal axis (V_{xx}) is parallel to the direction of the electric dipole moment of the H_2AsO_4 group.

The ^{75}As EFG tensors determined^{1,7,10,15} in ferroelectric KH_2AsO_4 and antiferroelectric $\text{NH}_4\text{H}_2\text{AsO}_4$ could be thus assigned to the six Slater¹⁶ H_2AsO_4 configurations predicted by the Slater–Nagamiya model¹⁶ of the phase transition in KH_2PO_4 . In ferroelectric KH_2AsO_4 both ‘close’ hydrogens are either attached to the ‘upper’ ($\mathbf{V}^{(1)}$) or to the ‘lower’ two H_2AsO_4 oxygens ($\mathbf{V}^{(2)}$) as viewed along the c axis,

so that the dipole moment points along $\pm c$. In antiferroelectric $\text{NH}_4\text{H}_2\text{AsO}_4$ on the other hand, one hydrogen is attached to the ‘upper’ and one to the ‘lower’ oxygen,

resulting in four ‘antiferroelectric’ H_2AsO_4 arrangements—($\mathbf{V}^{(3)}$, $\mathbf{V}^{(4)}$, $\mathbf{V}^{(5)}$, $\mathbf{V}^{(6)}$)—with dipole moments along the $\pm b$

Figure 10 (a) Temperature dependence of the ^{75}As NQR frequency ν_Q in KH_2AsO_4 on cooling through T_c . (b) Dependence of the inverse ^{75}As quadrupole coupling constant $(e^2qQ/h)^{-1}$ on $(T - T_c)/T_c$ in KH_2AsO_4 -type crystals above T_c

and $\pm a$ crystal axes. In the antiferroelectric domain, where the sublattice polarization $\vec{P} \parallel [100]$ is along the $\pm a$ axis, one sublattice corresponds to $\mathbf{V}^{(3)}$ and the other to $\mathbf{V}^{(4)}$, whereas for $\vec{P} \parallel [010]$ the corresponding EFG tensors are $\mathbf{V}^{(5)}$ and $\mathbf{V}^{(6)}$. These results represented the first direct proof that the antiferroelectric proton ordering suggested by Nagamiya¹⁶ is correct.

In the paraelectric phase each H_2AsO_4 group fluctuates between the six Slater configurations. The fluctuations result in a time averaging of the EFG tensors and in an anomalous increase in the ^{75}As spin–lattice relaxation rate as $T \rightarrow T_c$ ¹⁹ (Figure 11). The ^{75}As T_1^{-1} has been measured by the proton–arsenic cross-relaxation technique in the dipolar frame.¹⁷

3.6 Fluctuations at Cationic Sites

In contrast to the nuclei discussed so far which were all covalently bonded, the EFG tensor at the K, Cs or Rb sites in

Figure 11 Temperature dependence of the arsenic spin-lattice relaxation rate in the dipolar (rotating) frame as determined by proton-arsenic cross relaxation

KH₂PO₄-type ferroelectrics is of ionic character. These nuclei are thus nonlocal probes which measure the charge distribution and order on a scale of 40–50 unit cells (i.e. more than 10² O–H···O bonds). Here

$$\mathbf{V}_i = \mathbf{V}_i(p_1, p_2, \dots, p_L) \quad (20a)$$

The temperature dependence of the ¹³³Cs ($I = \frac{7}{2}$) quadrupole coupling constant in CsH₂AsO₄, for instance⁷ can be described above T_c by

$$\langle \mathbf{V}_i \rangle = \mathbf{V}_0 \quad T > T_c \quad (20b)$$

if the mean square fluctuations in the order parameter can be neglected. Below T_c , on the other hand, one finds

$$\langle \mathbf{V}_i \rangle = \mathbf{V}_0 + \mathbf{A}p + \mathbf{B}p^2 \quad T < T_c \quad (20c)$$

where the forms of the $\mathbf{V}_0$, $\mathbf{A}$, and $\mathbf{B}$ tensors are determined by crystal symmetry.^{7,18} Similar results are obtained for the ³⁹K and ⁸⁷Rb quadrupole coupling tensors in other KH₂PO₄-type crystals.¹

3.7 NMR in Perovskite Ferroelectrics

The local properties of phase transitions in perovskite-type ferroelectrics and antiferroelectrics have been extensively studied by NMR.²¹ Cottis and Knight²¹ and Hewitt²¹ were the first to study electric quadrupole interactions in perovskites.

Hewitt²¹ in particular measured the temperature dependence of the EFG tensor at the ⁹³Nb sites in KNbO₃. The spin-lattice relaxation studies of NaNbO₃²¹ gave important information on the softening of the collective rotations of the oxygen tetrahedra at the M point, $\mathbf{q} = (\frac{1}{2}, \frac{1}{2}, 0)$ —of the Brillouin zone.

4 NMR IN THE SLOW AND INTERMEDIATE MOTION REGIME

4.1 Dynamic Symmetry Breaking and NMR in KSCN, RbSCN, and NH₄SCN Antiferroelectrics

The second-order quadrupole shifts¹⁹ of the ³⁹K or ⁸⁷Rb $\frac{1}{2} \rightarrow -\frac{1}{2}$ NMR transitions in tetragonal KSCN and RbSCN show the effects of dynamic symmetry breaking on the NMR timescale.^{19,20} The symmetry of the angular rotation pattern in the high-temperature paraelectric tetragonal phase is lower than the K or Rb site symmetry as determined by X-ray scattering¹⁹ [Figure 12(a) and (b)]. At the same time the ³⁹K and ⁸⁷Rb ‘site’ and ‘90° domain’ doublet splittings which are proportional to the long range order parameter vanish above T_c [Figure 12(c)] as expected from equations (1a) and (1b).

The above systems undergo at T_c antiferroelectric–paraelectric phase transitions connected with a head–tail ordering of the SCN[−] groups. These groups are dynamically disordered above T_c and order in an antiparallel arrangement below T_c , resulting in a doubling of the unit cell size and the formation of 0, 90, 180, and 270° orthorhombic domains. The shift of the K⁺ or Rb⁺ ions from their position on the fourfold rotation axis is linearly coupled to the orientational degrees of freedom of the SCN[−] ions.

The NMR results¹⁹ show that for the second-order shifts and corresponding lineshapes the time fluctuating quadrupolar perturbation $\hat{\mathcal{H}}_Q^{(1)}(t)$, connected with the flipping of the SCN[−] groups, averages out in two steps.²⁰ This is because both diagonal and off-diagonal matrix elements—in the representation of eigenstates of the main Hamiltonian—are important. A resonance line is a doublet with a splitting $4A$ at very long correlation times ($A\tau \gg 1$) where the spectrum is the same as in the case of two static Hamiltonians

$$\hat{\mathcal{H}}_A = \hat{\mathcal{H}}_Z + \langle \hat{\mathcal{H}}_Q^{(0)} \rangle + \hat{\mathcal{H}}_Q^{(1)} \quad (21a)$$

and

$$\hat{\mathcal{H}}_B = \hat{\mathcal{H}}_Z + \langle \hat{\mathcal{H}}_Q^{(0)} \rangle - \hat{\mathcal{H}}_Q^{(1)} \quad (21b)$$

It becomes a singlet when τ^{-1} exceeds the doublet splitting, i.e. when $A\tau \ll 1$. The second-order shift of the resonance line caused by the off-diagonal matrix element of the quadrupolar perturbation $\hat{\mathcal{H}}_Q^{(1)}(t)$ vanishes, however, only when τ^{-1} exceeds the resonance frequencies ω_L of the main Hamiltonian, $\hat{\mathcal{H}}_Z + \langle \hat{\mathcal{H}}_Q^{(0)} \rangle$. For $A\tau \ll 1$, $\omega_L\tau \gg 1$ we are thus in the intermediate motion limit and have a partial motional averaging. The doublet splitting induced by $\hat{\mathcal{H}}_Q^{(1)}(t)$ is averaged

Figure 12 (a) Temperature dependence of the ^{39}K angular rotation pattern in KSCN for the c rotation above T_c and (b) below T_c . The domain splitting seen below T_c [inset to (b)] disappears above T_c whereas the angular dependence observed above T_c is incompatible with the tetragonal symmetry of the phase. (c) Temperature dependence of domain splitting

out, but the second-order quadrupolar shift induced by $\hat{\mathcal{H}}_Q^{(1)}(t)$ is still nonzero:

$$\Delta\omega_{1/2 \rightarrow -1/2}(\tau) = \Delta\omega_{1/2 \rightarrow -1/2}^{(0)} + \Delta\omega_{1/2 \rightarrow -1/2}^{(1)}(\tau) \quad (22a)$$

where

$$\Delta\omega_{1/2 \rightarrow -1/2}^{(1)}(\tau) \propto \frac{(\omega_L \tau)^2}{1 + (\omega_L \tau)^2} \quad (22b)$$

It is only in the fast motion limit, $\omega_L \tau \ll 1$, that $\Delta\omega_{1/2 \rightarrow -1/2}^{(1)}(\tau) \rightarrow 0$ and the angular dependence of the second-order quadrupolar shift is $\Delta\omega_{1/2 \rightarrow -1/2}^{(0)}$, i.e. it is determined by the time averaged Hamiltonian $\langle \hat{\mathcal{H}}_Q^{(0)} \rangle$.

In agreement with this model and equations (2a)–(3c), the ^{39}K and ^{87}Rb spin–lattice relaxation rates show no anomaly at T_c as all critical factors in equation (2b) cancel (Figure 13). T_1 is proportional to $\omega_L^2 \tau_0$, and continues to decrease with increasing temperature as the crystal is heated above T_c since τ_0 is thermally activated.

The dynamic symmetry breaking effects are not seen in the ^{14}N ($I = 1$) NMR in NH_4SCN ,¹⁹ as here first-order quadrupole splittings were studied where off-diagonal matrix elements are not important.

4.2 Dynamic Symmetry Breaking in KH_2AsO_4

In addition to the broad paraelectric arsenic lines, sharp ‘ferroelectric’ arsenic $\frac{1}{2} \rightarrow -\frac{1}{2}$ lines have been observed in KH_2AsO_4 well above T_c .¹⁵ The angular dependence of these lines shows that here the symmetry of the paraelectric phase is also broken on the timescale of the NMR Larmor frequency. In contrast to KSCN and RbSCN where—in view of the large moment of inertia of the SCN group and the correlations between the flips of different SCN^- groups induced by the small available space for single ion reorientations—the intrinsic dynamics are very slow, we have in KH_2AsO_4 a high frequency soft mode similarly as in KH_2PO_4 . The formation of nearly static polar clusters above T_c and the resulting dynamic symmetry breaking may thus be, in contrast to KSCN and RbSCN, induced here by defects.

Figure 13 Temperature dependence of the normalized ^{87}Rb NMR T_1 components in RbSCN

5 NMR IN PROTON AND DEUTERON GLASSES

5.1 Determination of the Edwards–Anderson Order

Parameter q_{EA} in the Fast Motion Limit

Solid solutions $\text{Rb}_{1-x}(\text{ND}_4)_x\text{D}_2\text{PO}_4$ (RADP) of ferroelectric RbH_2PO_4 and antiferroelectric $\text{ND}_4\text{D}_2\text{PO}_4$ represent a randomly frustrated hydrogen-bonded system with competing ferroelectric and antiferroelectric interactions. For $0.22 \leq x \leq 0.78$ the system forms a deuteron glass²¹ with no macroscopic symmetry breaking and no spontaneous polarization at any temperature. Here too the O–D···O bond represents a two-position reorientable dipole (see Figure 3) which can be described by an Ising pseudospin, $S^z = \pm 1$. In contrast to magnetic spin glasses where we deal with random bond interactions, proton and deuteron glasses are characterized by the presence of both random bonds and random fields²²

$$\hat{\mathcal{H}} = - \sum_{i < j} J_{ij} S_i^z S_j^z - \sum_i f_i S_i^z \quad (23)$$

Here the J_{ij} are quenched random interactions and f_i are quenched random fields characterized by their second cumulants $[J_{ij}^2]_{\text{AV}} = J^2/N$ and $[f_i f_j]_{\text{AV}} = \delta_{ij} \Delta$. The random bond distribution is assumed to be Gaussian and centered around a mean value $J_0 = J_{\text{AFEX}} + J_{\text{FE}}(1-x)$ where x represents the NH_4 concentration. J^2 and Δ , on the other hand, are proportional to $x(1-x)$ and vanish for $x \rightarrow 0$ and $x \rightarrow 1$. For $|J_0| < J$ the system forms a glass phase without long range order whereas for $|J_0| > J$ a long range ordered inhomogeneous ferroelectric or antiferroelectric phase is predicted to occur.

The basic question in deuteron glasses is how to measure the Edwards–Anderson order parameter²

$$q_{\text{EA}} = \frac{1}{N} \sum_i \langle S_i^z \rangle^2 \quad (24)$$

as there is no macroscopic conjugate field attached to it. The answer is provided by NMR. In the fast motion limit NMR also allows for a direct determination of the local polarization distribution function $W(p)$, the second moment of which is q_{EA} .

In the simplest case the local NMR frequency ω_i of the deuteron in an O–D···O bond is in the fast motion limit [$\omega_{\text{AB}} \tau \ll 1$, $\omega_{\text{AB}} = \omega_{\text{A}} - \omega_{\text{B}}$] linearly related to the pseudospin polarization $\langle S_i^z \rangle = p_i$ of this bond:

$$\omega_i = \omega_0 + \omega_1 \langle S_i^z \rangle = \omega_0 + \omega_1 p_i \quad (25)$$

O–D···O bonds with different local polarizations p_i will thus have different NMR frequencies resulting in an inhomogeneous broadening of the NMR line. The resulting frequency distribution,

$$f(\omega) = \frac{1}{N} \sum_i \delta(\omega - \omega_i) = [\delta(\omega - \omega_i)]_{\text{AV}} \quad (26)$$

is related to the local polarization distribution $W(p)$ [equation (4)] via

$$f(\omega) d\omega = W(p) dp \quad (27)$$

A measurement of $f(\omega)$ thus allows for a determination of $W(p)$ and its second moment q_{EA} if the relation between ω_i and p_i [equation (25)] is known from experiments on pure systems. q_{EA} in particular is obtained from

$$M_2[f(\omega)] = \int d\omega f(\omega) (\omega - \omega_0)^2 = \omega_1^2 q_{\text{EA}} \quad (28)$$

Such experiments have been indeed performed,⁴ and the results can be well described by the random bond–random field model.^{4,22} The temperature dependence of q_{EA} (Figure 14) in particular demonstrates that in contrast to magnetic spin glass, random fields are present in addition to random bonds. From the shape of the deuteron NMR spectrum [Figure 15(a)] the temperature dependence of $W(p)$ can be determined [Figure 15(b)]. $W(p)$ is here symmetric around $p = 0$ and changes from a single-peaked to double-peaked form with decreasing temperature.

At lower temperatures where the pseudospin fluctuations are no longer very fast as compared to the rigid lattice quadrupole splittings ω_{AB} , we have to take into account the additional broadening due to the slowing down of the fluctuations by convoluting $W(p)$ with the well known dynamic lineshape $I(\omega, p, \tau)$ for exchange in an asymmetric two-site potential. Equation (26) now becomes

$$f(\omega) = \int I(\omega, p, \tau) W(p) dp \quad (29)$$

When the fluctuations become too slow, $\omega_{\text{AB}} \tau \geq 1$, the second moment of the lineshape is no longer proportional to q_{EA} but

Figure 14 Temperature dependence of q_{EA} as determined from the second moment of the $^{87}\text{Rb } \frac{1}{2} \rightarrow -\frac{1}{2}$ NMR spectra in $\text{Rb}_{0.56}(\text{ND}_4)_{0.44}\text{D}_2\text{PO}_4$. The dotted line represents the fit to the random bond–random field model with $\Delta/J^2 = 0.35$, $T_g = J/k = 90$ K, whereas the dashed line represents the best fit for the pure random field model where $T_g = 0$ K and $\sqrt{\Delta}/k = 68.2$ K. The solid line represents the fit to the pure random bond model with $T_g = 151$ K and $\sqrt{\Delta}/k = 0$ K

Figure 15 (a) O–D···O deuteron NMR spectrum in $\text{Rb}_{0.56}(\text{ND}_4)_{0.44}\text{D}_2\text{PO}_4$ at various temperatures. (b) Temperature dependence of the local polarization distribution function $W(p)$ for $\text{Rb}_{0.56}(\text{ND}_4)_{0.44}\text{D}_2\text{PO}_4$ where $\Delta/J^2 = 0.35$

approaches a constant value determined by $I(\omega, p, \tau = \infty)$. Here 1D NMR cannot be used for a determination of q .

5.2 Determination of the Glass Order Parameter q in the Slow Motion Limit

In the slow motion limit where $\omega_{AB}\tau \gg 1$ the nucleus ‘sees’ the instantaneous value of the Hamiltonian corresponding to $S^z = \pm 1$. The NMR spectrum of the O–D···O bond deuteron will thus consist of two lines,

$$\omega_A = \omega_0 + \omega_1 \quad (30a)$$

and

$$\omega_B = \omega_0 - \omega_1 \quad (30b)$$

corresponding to the ‘left’ and ‘right’ position of the deuterons in the double-minimum hydrogen bond potentials. 2D ‘exchange’ NMR spectroscopy²³ can be used here to determine the glass order parameter q as well as the intrabond deuteron jump rate. The corresponding pulse sequence

Figure 16 2D exchange NMR pulse sequence²⁴

(Figure 16) developed by Spiess et al.²⁴ selects the signal of the form

$$\begin{aligned} F(t_1, t_2, t_m) = & \exp(-t_m/T_1) \exp[-(t_1 + t_2)/T_2] \\ & \times [a_{AA}(t_m) \cos(\omega_A t_1) \cos(\omega_A t_2) \\ & + a_{BB}(t_m) \cos(\omega_B t_1) \cos(\omega_B t_2) \\ & + a_{AB}(t_m) \cos(\omega_A t_1) \cos(\omega_B t_2) \\ & + a_{BA}(t_m) \cos(\omega_B t_1) \cos(\omega_A t_2)] \quad (31) \end{aligned}$$

After a Fourier transformation with respect to t_1 and t_2 the results are presented in the $\omega_1 - \omega_2$ plane. If no intrabond deuteron exchange, $A \leftrightarrow B$, has taken place the absorption peaks lie on the diagonal of the $\omega_1 - \omega_2$ plane at (ω_A, ω_A) and (ω_B, ω_B) . If intrabond deuteron transfer has taken place between the two physically nonequivalent sites A and B, we also find cross peaks at (ω_A, ω_B) and (ω_B, ω_A) . The intensities of the cross peaks (Figure 17) are proportional to the fraction of nuclei that have undergone exchange in the time t_m . Since

$$a_{AA}(\infty) = \frac{1}{N} \sum_i W_{Ai}^2 \quad (32a)$$

$$a_{BB}(\infty) = \frac{1}{N} \sum_i W_{Bi}^2 \quad (32b)$$

and

$$a_{AB}(\infty) = a_{BA}(\infty) = \frac{1}{N} \sum_i W_{Ai} W_{Bi} \quad (32c)$$

where W_{Ai} is the probability of finding the deuteron of the i th O–D···O bond in site A, etc., we get for the ratio of the intensities of the cross peaks to the diagonal peaks in the limit $t_m \rightarrow \infty$ the expression

$$R(t_m \rightarrow \infty) = \frac{a_{AB}(\infty)}{a_{AA}(\infty)} = \frac{\sum_i W_{Ai} W_{Bi}}{\sum_i W_{Ai}^2} \quad (33a)$$

Using $\langle S_i^z \rangle = W_{Ai} - W_{Bi}$ and

$$q = \frac{1}{N} \sum_i \langle S_i^z \rangle^2 = \frac{1}{N} \sum_i (W_{Ai} - W_{Bi})^2 \quad (33b)$$

as well as

$$\frac{1}{N} \sum_i (W_{Ai} + W_{Bi})^2 = 1 \quad (33c)$$

Figure 17 2D O–D...O intrabond deuteron ‘exchange’ NMR spectra of $\text{Rb}_{0.68}(\text{ND}_4)_{0.32}\text{D}_2\text{AsO}_4$ for $\mathbf{a} \perp \mathbf{B}_0$, $\angle(\mathbf{b}, \mathbf{B}_0) = 45^\circ$ at $T = 40$ K showing the gradual appearance of cross peaks with increasing mixing time

and $a_{AA} = a_{BB}$, equation (33a) can be rewritten as

$$R(t_m \rightarrow \infty) = \frac{1 - q}{1 + q} \quad (34)$$

A measurement of $R(t_m \rightarrow \infty)$ thus allows for a determination of q in the slow motion limit.²³

The time evolution of $R(t_m) = a_{BA} / a_{AA}$, on the other hand (Figure 18), allows for a direct site specific measurement of

Figure 18 Ratio of cross peak to diagonal peak intensity R as a function of the mixing time t_m at $T = 40$ K. The same curve is obtained for different crystal orientations with different ω_{AB} splittings so that spin diffusion is excluded

the deuteron intra-hydrogen bond exchange rates, $A \rightarrow B$:

$$R(x) = \tanh x \quad x = t_m / \tau \quad (35)$$

The observed intra-hydrogen bond deuteron exchange times²³ vary from 14.4 s at $T = 45$ K to 235 s at $T = 24$ K. The motion is thermally activated with $E_a = 12.8$ meV and $\tau_0 = 0.43$ s, showing that phonon assisted deuteron tunneling may be important.

6 NMR DETERMINATION OF ORDER PARAMETERS IN INHOMOGENEOUS FERROELECTRICS

For $0 \leq x < x_{FE}$ or $x_{AFE} \leq x \leq 1$ (see Figure 2) where $|J_0| > J$ a long-range ordered inhomogeneous ferroelectric or antiferroelectric phase exists below T_c . Here long-range and glassy order should coexist below T_c . Above T_c , long-range order vanishes whereas glassy order should persist. The glassy state is characterized above T_c by the Edwards–Andersons parameter q_{EA} and below T_c by $\tilde{q}_{EA} = q_{EA} - P^2$, i.e. by the difference between the EA order parameter and the square of spontaneous polarization P^2 . Both $\tilde{q}_{EA}$ and q_{EA} have been determined²⁵ by ^{75}As NQR ($T < T_c$) and quadrupole perturbed NMR ($T > T_c$) in $\text{Rb}_{1-x}(\text{NH}_4)_x\text{H}_2\text{AsO}_4$ for $x = 0.01$ and $x = 0.02$.

In pure RbH_2AsO_4 the experimentally measured temperature dependences of the spontaneous polarization $P = P(T)$ and the ^{75}As NQR frequency $\nu_Q(T)$ determine the relationship $\nu_Q = \nu_Q(P)$. In a mixed crystal in the weak disorder limit $x \rightarrow 0$ the $\nu_Q = \nu_Q(P)$ relation for the mean NQR frequency is the same as in the pure crystal. In the general case we replace the reduced spontaneous polarization $\bar{P} = P/P(T = 0)$ by the local polarization p . We thus have

$$\omega_Q = \omega_0 + \omega_2 p^2 + \omega_4 p^4 \quad (36)$$

Figure 19 Experimental and theoretical ^{75}As NQR lineshapes²⁵ in $\text{Rb}_{1-x}(\text{NH}_4)_x\text{H}_2\text{PO}_4$ for $x = 0.00$ and $x = 0.02$ for $T < T_c$

Figure 20 Temperature dependence²⁵ of q_{EA} and $\tilde{q}_{EA} = q_{EA} - P^2$ in $Rb_{1-x}(NH_4)_xH_2AsO_4$ for $x = 0.02$. Theoretical fits are shown as solid lines

as the ^{75}As NQR frequency is invariant with respect to the sign reversal of p . The temperature dependence of the mean ^{75}As NQR frequency thus yields the long-range order parameter P whereas the inhomogeneous ^{75}As NQR lineshape yields the local polarization distribution function $W(p)$, and its second moment q_{EA} , via

$$f(\omega) = W(p)|d\omega/dp|^{-1} \quad (37)$$

The ^{75}As pure NQR lineshapes of $Rb_{1-x}(NH_4)_xH_2AsO_4$ for $T < T_c$ are shown in Figure 19 for $x = 0.00$ and $x = 0.02$ together with the theoretical fits obtained from the compressible random bond–random field pseudospin Ising model.²⁵ In contrast to the case of proton and deuteron glasses ($|J_0| < J$) the local polarization distribution function $W(p)$ is asymmetric with respect to $p = 0$ here.

The temperature dependence of q_{EA} and $\tilde{q}_{EA} = q_{EA} - P^2$ for $x = 0.02$ is shown in Figure 20. The theoretical fits are shown as solid lines. The jump in q_{EA} at T_c demonstrates the occurrence of a first-order phase transition.

Theoretical fits demonstrate that random bond effects dominate random field effects thus proving the existence of a collective glassy state in inhomogeneous ferroelectrics even in the weak substitutional disorder limit.

1 INTRODUCTION

The structure and dynamics of oxygen-containing compounds is a subject of widespread significance. Compared with ^1H , ^{13}C , ^{31}P , and ^{19}F NMR, however, ^{17}O NMR has received little attention.^{1–8} This neglect is not surprising since, of the naturally occurring oxygen isotopes, only ^{17}O possesses a nuclear spin ($I = \frac{5}{2}$). Due to its electric quadrupole moment ($Q_e = -2.6 \times 10^{-30} \text{ e m}^2$), its low natural abundance (0.037%), and the extremely low absolute sensitivity compared with that of ^1H (about 1.1×10^{-5}), the ^{17}O isotope is one of the more difficult nuclei to observe by NMR spectroscopy. It is, however, of great interest to use a nucleus such as oxygen that is located at strategic molecular sites and is directly involved in inter- and intramolecular interactions. The ^{17}O NMR parameters, i.e. isotropic shielding, principal elements of the ^{17}O shielding and electric field gradient tensors, and the transverse and longitudinal relaxation times, can be considered as excellent means of probing the structure, bonding, and dynamics of oxygen-containing compounds. Furthermore, recent advances in instrumentation, the extremely large chemical shift scale (which aids in the resolution of quadrupole broadened resonances), and the availability of ^{17}O enriched compounds have alleviated these difficulties; thus, an increased use of the ^{17}O NMR technique can be envisaged.^{9–11}

2 EXPERIMENTAL ASPECTS

2.1 The Case of ^{17}O Enrichment

The stringent requirements in studies of compounds at natural abundance are the high concentrations ($>0.1 \text{ M}$) and extensive signal averaging needed.¹² Recording of spectra can be greatly facilitated by the use of ^{17}O enriched samples (Figure 1). When using FT high field instruments and ^{17}O labeled compounds (^{17}O enrichment 10–40 atom %), concentrations of greater than 1 mM are desirable, depending on the linewidths. Synthesis involving oxygen isotopes tends to involve rather straightforward organic reactions. However, one caveat that should be kept in mind when contemplating the synthesis of an ^{17}O labeled compound is the expense

Figure 1 ^{17}O NMR spectra (48.8 MHz; 40 °C) of N -[^{17}O]acetyl-L-proline.¹³ (a) 10% enrichment, 0.1 M in aqueous solution containing 1 M NaCl and $5 \times 10^{-5} \text{ M}$ EDTA; $T_{\text{acq}} = 12 \text{ ms}$, NS = 300 000, total experimental time = 1 h: (upper trace) normal spectrum; (lower trace) after a Gaussian-exponential resolution enhancement. (b) 1% enrichment, 0.1 M in methanol, $T_{\text{acq}} = 10 \text{ ms}$, NS = 200 000, total experimental time = 32 min, line broadening (LB) = 50 Hz. (c) 0.4 M natural abundance in acetone (the asterisk marks the carboxyl oxygen resonance); $T_{\text{acq}} = 5 \text{ ms}$, number of scans (NS) = 1 900 000, total experimental time $\approx 10 \text{ h}$, LB = 50 Hz; (d) 1% enrichment, 0.1 M in acetone; $T_{\text{acq}} = 10 \text{ ms}$, NS = 1 350 000, total experimental time $\approx 8 \text{ h}$, LB = 50 Hz. (Adapted by permission of The American Chemical Society from R. N. Hunston, I. P. Gerothanassis, and J. Lauterwein, *J. Am. Chem. Soc.*, 1985, **107**, 2654)

of the starting reagents. Simple modifications of existing reactions are required. For example, $^{17}\text{O}_2$, C^{17}O , or C^{17}O_2 , is added to evacuated systems, as opposed to more traditional procedures which involve bubbling through the reaction mixture. Recently, a comprehensive overview of ^{17}O enriched methods has been published.¹⁴

2.2 Referencing Techniques

As with many heteronuclei, a variety of reference compounds and referencing procedures (both internal and external) have been suggested for ^{17}O NMR. For diamagnetic solutions, an external standard in a combined use of two cylindrical cells has been recommended.¹⁵ Using this technique, doubly distilled water or 1,4-dioxane can be used as external reference. Both compounds have chemical shifts which are indistinguishable at 30–40 °C and their magnetic susceptibility correction is small (<0.6 ppm) relative to common organic solvents. However, H_2O has the disadvantage that its chemical shift varies with temperature (–3 ppm between 27 and 90 °C) due to cleavage of intermolecular hydrogen bonds (the same applies for D_2O in addition to an isotopic effect of –3 ppm).

2.3 Solvent (H_2O) Suppression

Perhaps the most straightforward approach to solvent suppression is the use of ^{17}O depleted water, provided of course that rapid ^{17}O exchange does not occur between solvent and solute.¹⁶ Further suppression can be achieved by exploiting the special relaxation properties of the solvent, by postexperiment data processing and by selectively exciting the whole spectrum apart from that of the solvent.¹⁷ A critical note on the usefulness of the selective excitation pulse sequences in ^{17}O NMR has recently been published.¹⁸

2.4 Acoustic Ringing

Observation of very broad resonances in NMR is a potential problem due to baseline distortions. The most severe of the baseline artifacts is that due to the transient response of the NMR probe, often referred to as ‘acoustic ringing’, caused by the generation of ultrasonic waves from the action of the rf pulse. In the last decade, several pulse sequences designed for the suppression of acoustic ringing have been reported, and the reader should consult a relevant review article for details.¹⁹ For experiments in solution, the extended spin echo sequence was found to be particularly useful, since it utilizes minimum pulse and preacquisition delay times. A closely related pulse sequence for experiments in the solid phase has also been suggested.²⁰

3 CHARACTERISTIC PARAMETERS

3.1 Chemical Shifts

3.1.1 Experimental Shielding Ranges: Empirical Correlations

A general pattern of ^{17}O shielding is shown in Figure 2. For compounds containing oxygen bonded only to carbon and/or hydrogen there is a clear correlation between the C–O π bond order and a high frequency shift.²¹ This type of correlation arises from the multiple bond term $\Sigma_{B \neq A} Q_{AB}$ in the Karplus–Pople equation.²² For bridging oxygen atoms, a strong deshielding is observed when the substituents R are replaced by π -accepting acyl substituents which introduce π

Figure 2 ^{17}O chemical shift ranges for different X–O bonds. (Adapted by permission of Plenum Press from W. McFarlane and H. C. E. McFarlane, in ‘Multinuclear NMR’, ed. J. Mason, 1987, Chap. 14)

character into the C–O bond of the bridging oxygen. Thus, bridging oxygen resonances in carbonates and esters appear at high frequency relative to the corresponding resonances in alcohols, ethers, and acetals. An even greater high frequency shift is observed for anhydrides, where bridging oxygen atoms are bonded to two π acceptors. If chemical shifts are assumed to depend linearly on π bond order, the chemical shift of about 600 ppm for aliphatic aldehydes (π bond order of about 1) relative to water (π bond of 0) implies a chemical shift of about 200 ppm for CO_3^{2-} (π bond order of $\frac{1}{3}$). The observed shift of CO_3^{2-} (192 ppm) is in agreement with this crude prediction, further supporting the general correlation between π bond order and shielding discussed above.²

In nitrogen-containing compounds, as in carbon compounds, chemical shift values are determined largely by π bonding effects.^{23–25} Bridging oxygen resonances are observed at even higher frequency in nitrates, where π bonding is appreciable. A lesser, but nonetheless significant, effect is observed for bridging oxygen atoms in nitrates. The most striking feature of the ^{17}O shifts observed for P–O bonds is the small chemical shift range (20–260 ppm) which cannot be related to P–O bond order in a straightforward fashion. However, ^{17}O resonances for nonequivalent oxygen atoms in phosphates and polyphosphates can be resolved and have been used in stereochemical and binding site studies.^{26–28} For S–O bonding, similar trends to those displayed by P–O bonds are observed. Modification of the π bond order in an X=O group due to substituents on X results in a decrease (or increase) in the net charge on X as the charge on oxygen increases (or decreases). The chemical shift variations experienced by the nuclei X and O are then opposite and roughly proportional to the ratio $\langle r^{-3} \rangle_{2\text{px}} / \langle r^{-3} \rangle_{2\text{pO}}$.²⁴ For a series of oxyanions and a series of C=O and N=O compounds a linear correlation has been found between $\delta(^{17}\text{O})$ and the variation in ΔE^{-1} .²⁹ A linear correlation exists between acetone chemical shifts and the first maximum of the $n \rightarrow \pi^*$ transition for acetone/water

solutions³⁰ and for acetone in different solvents.³¹ Similar trends have also been observed in a variety of substituted acetophenones;³² however, it was suggested that such trends may be fortuitous, since the transition energy depends upon the balance of several effects associated with both π donation and σ withdrawal.³³ From a study on a series of aliphatic ethers, a correlation between $\delta(^{17}\text{O})$ and the first ionization potential has been suggested.³⁴

Compounds containing oxygen–oxygen bonds and oxygen–fluorine bonds display large high-frequency shifts.^{35–37} The ability, therefore, of ^{17}O NMR to distinguish unambiguously between nonequivalent oxygen atoms has found application in several structural and mechanistic studies. The same applies to oxygen bonded to transition metals (see below). Empirical correlations were extended to diamagnetic transition metal anions of the general formula MO_4^{n-} , and theoretical calculations were carried out to show that the absolute magnitude was reasonable.²⁹

3.1.2 Theory of ^{17}O Chemical Shifts (see *Shielding: Overview of Theoretical Methods*)

3.1.2.1 Isolated Molecules. Ab initio calculations^{38,39} of ^{17}O nuclear shielding tensors have been reported for a variety of simple molecules such as H_2O , CH_3OH , $(\text{CH}_3)_2\text{O}$, H_2CO , CH_3CHO , HCONH_2 , and CO . The results are gauge dependent and in many cases vary considerably depending on the basis set used. Gauge independent ab initio results for H_2O and H_2CO indicate a ^{17}O shielding of 757.6, 860.3, or 858.8 ppm for H_2CO , with respect to H_2O , compared with the experimental result of 580–600 ppm. The calculated data represent a choice of three basis sets. Semiempirical INDO (intermediate neglect of differential overlap) calculations are numerically smaller than the experimental results, whereas the CNDO/S (complete neglect of differential overlap/S) calculations produce better overall agreement.^{40–43} This probably reflects an insensitivity of the INDO orbital energies to changes in the environment of the oxygen. By omitting those molecules and ions which have nitrogen directly bonded to oxygen the CNDO/S results gave a standard deviation of 30.6 ppm and a correlation coefficient of 0.98 compared with the experimental values. Analysis of the CNDO/S results demonstrates that the ^{17}O shielding differences of some carbonyl compounds are dominated by the lowest energy $n \rightarrow \pi^*$ transition. For the linear species CO , CO_2 , and NO_2^+ , the largest contribution to the paramagnetic part σ_p of the ^{17}O shieldings arises from the lowest energy $\sigma \rightarrow \pi^*$ transition. Similarly, for the bent ion NO_2^- the lowest energy $\sigma \rightarrow \pi^*$ transitions are dominant for the in-plane components of the shielding tensor, while the out-of-plane contribution is controlled by $\sigma \rightarrow \sigma^*$ transitions. In general, these ^{17}O shieldings are in reasonable agreement with the available experimental data, and in some cases are an improvement upon ab initio results. Analogous calculations employing a basis set of gauge dependent atomic orbitals within the CNDO/2 framework have been reported for ^{17}O shieldings in electrolyte solutions.⁴⁴ For ozone,⁴⁵ the use of localized molecular orbitals within the IGLO method (see *Shielding Calculations: IGLO Method*) allows the contributions to the total shielding to be partitioned into orbital contributions, so that the specific role played by the lone pairs on the atom in question and orbitals centered on neighboring atoms can be discerned.⁴⁶ The calculated shieldings for O_3

were found to be extremely large, highly anisotropic, and to differ from the experimental values by a factor of 2–3. The authors also noted that the paramagnetic contributions are mainly due to the lone pairs on the respective oxygen atoms, unlike the triatomic molecules CO_2 and FNO in which the paramagnetic contributions are mainly due to the bonds interacting with the antibonding π^* electrons and only to a limited extent to the lone pairs.

3.1.2.2 Solvent and medium effects. Recently, the effect of electrical polarization on the chemical shielding of carbon monoxide has been considered in detail.^{47,48} In addition, the relationship between the vibrational frequency and the shieldings for three different types of electrical environments—a uniform field, a field gradient, and an axial point-charge dipole—together with experimental ^{13}C and ^{17}O isotropic shieldings and vibrational frequencies for a range of carbon monoxide derivatives of heme proteins has been described. For each type of environment, the shieldings vary linearly with the vibrational frequency for a relatively wide range of frequency shifts.⁴⁸ This shows, in agreement with experiment,⁴⁹ that there is a linear relationship that is opposite for ^{13}C and ^{17}O .⁵⁰

The effects of solvents on the ^{17}O nuclear shielding of solute molecules may be categorized into hydrogen-bonding interactions and influences that arise from electronic interactions between the dipole moments of the solute and solvent molecules. Precise mathematical expressions are not available for many nonbonded interactions. Consequently, continuum models tend to be more popular for investigating solvent effects on NMR parameters. The most widely used of these, to date, is the solvaton model.⁵¹ By means of this model the solute–solvent interaction can be included in the paramagnetic screening contribution, and the solvent induced shift is proportional to $(\epsilon - 1)/2\epsilon$, where ϵ is the dielectric constant of the medium. Some sum-over-states (SOS) and finite perturbation theory (FPT) calculations of oxygen nuclear shieldings of several organic functional groups, as obtained using the solvaton model, predict increases in shielding as ϵ increases.^{50,52} An analysis of the various factors contributing to the paramagnetic term reveals that the increase in shielding arises from a concomitant decrease in $\langle r^{-3} \rangle_{2p}$ and an increase in the weighted average of the energies of the various transitions contributing to the paramagnetic term. The observed decrease in $\langle r^{-3} \rangle_{2p}$ is consistent with an increase in the average separation between the nucleus and its 2p electrons as the charge q increases. The increase in the weighted averaged of the transition energies is largely controlled by the increase in energy of the lowest $n \rightarrow \pi^*$ transition as the extent of solvation increases.

The shielding of the ^{17}O nuclei of several functional groups are quite sensitive to hydrogen-bonding interactions. From a theoretical standpoint the shielding may be considered by using the supermolecule approach. A good example is provided by formamide.⁵³ Ab initio calculations using GIAOs (gauge invariant atomic orbitals) within the FPT framework have been reported for formamide (FMA) in the presence of its first hydration shell. The ^{17}O shielding values reported for the complexes $\text{FMA}-(\text{H}_2\text{O})_2$ show that the shift observed when the oxygen atom is directly involved in the hydrogen bond is much larger than the one occurring when the water molecules are bound to the NH group. The variation was calculated to be to low frequency in both cases. This is in agreement with

^{17}O NMR experimental data on FMA and several amides in different solvents.

3.2 Indirect Spin Coupling Constants

Because of the breadth of ^{17}O resonances, only relatively large coupling constants can be measured, and hence the majority of those recorded refer to couplings from directly bonded nuclei. $^1J(\text{O},\text{H})$ in water and alcohols has values close to 80 Hz.^{54–56} The $^1J(\text{P},\text{O})$ couplings involving $\text{P}=\text{O}$ groups cover a fairly wide range (145–210 Hz) and for a series of compounds of type OPX_3 ($\text{X} = \text{F}$ or O in OMe , $\text{X} = \text{N}$ in NMe_2 , and $\text{X} = \text{C}$ in Me) there is a consistent drop in coupling with decreasing electronegativity of X . This may be qualitatively attributed to the electronegative substituents removing electrons in outer orbitals from the phosphorus atom, leading to a greater effective atomic charge and hence stronger contact interaction between the phosphorus nucleus and the s orbitals. A finite perturbation theoretical treatment within the CNDO/2 formalism has reproduced the observed trends, but not the absolute values.⁵⁷ The oxygen atoms in $\text{P}-\text{OMe}$ groups within phosphates give rise to a consistently smaller coupling constant, compared with $\text{P}=\text{O}$, of between 90 and 100 Hz; there is an indication of a considerably larger value for phosphites. The reduced coupling constants decrease with increasing atomic number of the central atoms along the isoelectronic sequence VO_4^{3-} , CrO_4^{2-} , and MnO_4^- .⁵⁸ The values of ^{17}O spin–spin couplings have been used to investigate H_3O^+ species.⁵⁹ The ^{17}O NMR spectrum revealed a perfect quartet with $J(\text{O},\text{H}) = 107$ Hz. Furthermore, the effect of H/D substitution is evident in the ^{17}O NMR spectra of $\text{H}_2\text{O}-\text{D}_2\text{O}$ in CH_2Cl_2 . Thus, the species H_2O , HDO , and D_2O could be identified from coupling constants, without reference to chemical shift data.⁶⁰ 2J couplings are normally about an order of magnitude smaller than the corresponding directly bonded couplings.⁶¹ However, there seems to be a particularly favored coupling pathway from hydrogen to the ‘ether’ oxygen atom in HCOOR systems, which is probably associated with π bonding across the planar framework.

In some cases coupled resonances cannot be resolved into fine structure but exhibit a partially collapsed structure, depending on the rate of proton transfer. In such cases decoupling of the other nuclei can lead to reduced linewidths and information about coupling constants.

When a spin- $\frac{1}{2}$ nucleus is bonded directly to ^{17}O , the X nucleus will also be relaxed by virtue of its spin–spin coupling with ^{17}O . This has been termed ‘scalar relaxation of the second kind’. Such a line-broadening effect for ^{17}O in ^{31}P NMR has been used to locate the position of the ^{17}O label and to calculate the percentage enrichment of ^{17}O . In addition, it has made possible analysis of the configuration of (^{16}O , ^{17}O , and ^{18}O) phosphate monoesters and (^{16}O , ^{17}O , and ^{18}O) thiophosphates by ^{31}P NMR.^{62–64}

3.3 Nuclear Quadrupole Coupling Constants

The electrostatic interaction between the nuclear quadrupole electric moment Qe and the electric field gradient tensor eq_{ij} is the quadrupolar interaction. An appropriate reference axis system can be chosen to reduce this interaction to two values:⁴ the main component

$$\chi = e^2 q_{zz} Q / h \quad (1)$$

and the asymmetry parameter (dimensionless)

$$\eta = (e^2 q_{xx} Q - e^2 q_{yy} Q) / e^2 q_{zz} Q \quad (2)$$

where $|e^2 q_{zz} Q| > |e^2 q_{yy} Q| > |e^2 q_{xx} Q|$.

The χ values for ^{17}O may be calculated by computing the field gradient from molecular wavefunctions and using the nuclear quadrupole moment Qe . Only relatively small molecules have been studied. Thus the calculated χ value for CO using the GAUSSIAN 88 program at the 6-31G* level⁴⁹ (3.1 MHz) was found to deviate from the experimental value (~ 4.4 MHz) (the value of 3.9 MHz obtained from ab initio calculations⁴⁷ is in better agreement with the experimental value). Furthermore, it was shown that hydrogen bonding to HF results in a significant decrease in χ of about 0.7 MHz for the linear species $\text{CO} \cdots \text{HF}$.

Semiempirical methods of various degrees of sophistication have been used to compute electric field gradients. Within the framework of the Townes–Dailey theory, the three components of the field gradient can be related to the electronic populations in the orbitals describing the oxygen bonding and to eq , the field gradient created by an electron in a $2p$ atomic orbital (the contribution from the valence s electrons is neglected because of the spherical symmetry). More elaborate models incorporate hybridization of atomic orbitals into valence bonding and lone pair orbitals. Such studies include the determination of σ and π orbital populations for $\text{X}-\text{O}$ bonds ($\text{X} = \text{C}, \text{N}, \text{P}$, or S).^{65,66}

The majority of experimentally determined χ and η values have been obtained in the solid state by the use of NQR spectroscopy; however, some have been determined by NMR measurements on powders or single crystals, where χ is small with respect to the NMR frequency. Quadrupole coupling constants have also been derived from the splittings in the ^{17}O spectra of molecules partially oriented in an electric field⁶⁷ or dissolved in a nematic liquid crystal.^{68,69} Detailed studies of polynuclear osmium carbonyl dynamics have been undertaken and together with ^{13}C measurements have provided estimates of the ^{17}O quadrupole coupling constants.⁷⁰ In molybdenum hexacarbonyl, the ^{95}Mo and ^{97}Mo linewidths gave the reorientational correlation time, which in turn made it possible to determine the χ values from the ^{17}O linewidth.⁷¹

Experimental χ values cover the range -8 to 17 MHz. The sign of χ is irrelevant to the NMR experiment, but from a theoretical point of view it gives information about the orientation of the field gradient. The experimental χ values for a series of compounds in the solid state that contain $\text{C}=\text{O}$, $-\text{O}-$, $\text{P}-\text{O}$, $\text{N}-\text{O}$, or $\text{S}-\text{O}$ bonds show the following trends:⁶

1. For substituted nitrophenols, hydroxybenzaldehydes, and nitrobenzaldehydes, the χ values are nearly invariant with the electronic properties of the substituent, but are reduced by hydrogen bonding.
2. Strong hydrogen bonding reduces the χ values by as much as 2.6 MHz.

In summary, the following scale of χ values has been suggested:

The ^{17}O χ values for the terminal CO groups in metallocarbonyls were found to be 1–3 MHz, although values below 0.1 MHz have also been observed. It was suggested that increased $d\pi - p\pi$ back-bonding from the metal will increase electron density perpendicular to the C–O axis and so reduce the χ values.⁷²

3.4 Relaxation Properties (see *Relaxation Theory for Quadrupolar Nuclei*)

3.4.1 Relaxation in the Extreme Narrowing Condition

In isotropic systems and in the absence of chemical exchange, the T_1 and T_2 relaxation times are equal and are given by

$$1/T_1 = 1/T_2 = 3/125(1 + \eta^2/3)\chi^2 f(\omega, D) \quad (3)$$

where χ is the nuclear quadrupole coupling constant. The asymmetry parameter η varies from 0 to 1 and describes the deviation of the electric field gradient from axial symmetry. $f(\omega, D)$ is the correlation function, which depends on the rotational diffusion constant D and its relative orientation with respect to the principal axes of the field gradient tensor. When isotropic reorientation is assumed, $f(\omega, D)$ reduces to the single correlation time τ_c . If the resonance absorption is a Lorentzian lineshape, the linewidth at halfheight $\Delta\nu_{1/2}$ is a direct measure of the relaxation time, provided that unresolved indirect spin coupling is not present and that chemical exchange phenomena do not take place. From equation (3) it is clear that the product $\chi^2(1 + \eta^2/3)$ can be obtained from ^{17}O relaxation times if the correlation time governing the relaxation is known. The Debye formula allows only the determination of the correct order of magnitude of τ_c . More precise values of τ_c could be obtained from the relaxation of other nuclei, such as ^{13}C or other quadrupolar nuclei; however, one should be aware of possible anisotropic reorientations due to molecular tumbling.⁴

3.4.2 Relaxation Outside the Extreme Narrowing Condition

In this case, the decay of the longitudinal (M_1) and transverse (M_2) magnetizations is no longer exponential but may be written as a weighted sum of $I + \frac{1}{2}$ exponentials:⁷³

$$M_1(t) = M_1(\infty) \left\{ 1 - k \left[\sum_{i=1}^{I+1/2} C_{1,i} \exp(-R_{1,i}t) \right] \right\} \quad (4)$$

$$M_2(t) = M_2(0) \left[\sum_{i=1}^{I+1/2} C_{2,i} \exp(-R_{2,i}t) \right] \quad (5)$$

Figure 3 Longitudinal (a) and transverse (b) relaxation of spin- $\frac{5}{2}$ nuclei in the absence of chemical exchange. The upper plots show the normalized amplitudes $C_{1,i}$ and $C_{2,i}$ of the three exponential components as a function of $\omega_0 \tau_c$ (coefficients 2 and 3 are plotted on the expanded scale given to the right). The lower plots show the relaxation rates as a function of the same parameter. (Adapted by permission of The American Institute of Physics from T. E. Bull, S. Forsen, and D. L. Turner, *J. Chem. Phys.*, 1979, **70**, 3106)

where $\sum_{i=1}^{I+1/2} C_{j,i}$ and $k = 2$ for an inversion–recovery experiment. Furthermore, although equation (4) is valid for the total magnetization, the decays of the individual components will normally not be exponential and will also depend on the length of the monitoring pulse. Equations (4) and (5) cannot be solved analytically, but must be solved numerically for each value of $\omega_0^2 \tau_c^2$. Figure 3 illustrates the longitudinal and transverse relaxation of spin $I = \frac{5}{2}$ nuclei in the absence of chemical exchange. The longitudinal relaxation may be regarded as a single exponential, within the limits of experimental error, for all correlation times. Conversely, the transverse relaxation is governed by the three contributions and the weights of the different contributions have similar magnitudes for the longer correlation times. For values of $\omega_0^2 \tau_c^2 \ll 1$, the transverse relaxation is approximately a single exponential. In the slow motion limit the rapid decay of the third component at longer correlation times may allow analysis in terms of just two exponential terms.

In addition to nonexponential relaxation for quadrupolar nuclei under conditions of nonextreme narrowing, the NMR signal will also be modified by shift changes which have been termed ‘second-order dynamic frequency shifts’ (see *Quadrupolar Interactions and Dynamic Frequency Shift*). Although long recognized theoretically, the experimental demonstration of such a phenomenon is not straightforward, since the symmetry of the composite peak is in practice difficult to distinguish from small phase misadjustment and is thus usually overlooked. Furthermore, strongly relaxed transitions may decay so quickly as to be undetected if the instrument deadtime is too long. Expressions for the NMR bandsape for $I = \frac{5}{2}$ and $I = \frac{7}{2}$ nuclei have been derived, both in the presence and the absence of chemical exchange.⁷⁴ In the limit $\omega_0 \tau_c \gg 1$, the $m = \frac{1}{2} \rightarrow m = -\frac{1}{2}$ component will dominate the spectrum because it is much narrower than the other components. This narrow signal will be shifted

towards lower frequency with a value proportional to χ^2/ω_0 . Between these two limits the resonance will be more or less asymmetric, with an apparent shift to either high or low frequency depending on the values of ω_0 , τ_c , and χ . The ratio of the dynamic shift to the linewidth $\Delta\omega_d/\Delta\omega_{\frac{1}{2}}$ in this region depends only on ω_0 and τ_c .

3.4.3 Effects of Relaxation Mechanisms Other Than Quadrupolar

It is evident from Figure 3 that the linewidth of the narrow component decreases as τ_c increases in the slow motion limit, while the linewidths of the intermediate and broad components increase. However, the linewidth of the narrow component does not necessarily decrease as τ_c increases if the chemical shift anisotropy is large. Such behavior has been observed in studies of the temperature and magnetic field strength dependence of ^{17}O NMR spectra of myoglobin MbC ^{17}O samples.⁷⁵ For $\tau_c \simeq 14$ ns and $\sigma_{\parallel} - \sigma_{\perp} = 800$ ppm (which is the value for a model heme compound obtained from NMR studies in the solid state) a CSA contribution to the linewidth of about 100 Hz was obtained for the narrow components. This value is comparable to that of the pure quadrupolar contribution to the linewidth (about 96 Hz). The CSA contribution to T_1 was found to be negligible (about 170 ms).

4 SELECTED APPLICATIONS

4.1 Dynamic and Kinetic Studies

Numerous dynamic and kinetic studies have been performed using ^{17}O NMR. Lineshape analysis is not straightforward because the linewidth itself is temperature dependent. Nevertheless, it has been shown that dynamic ^{17}O NMR is a convenient alternative to ^{13}C NMR for studies of metal carbonyl compounds.⁷⁶ A solution of $\text{HFeCO}_3(\text{CO})_{12}$ at -89°C gives only two ^{13}CO signals in a ratio of 1:2 instead of the expected four signals with a 1:1:1:1 ratio. In ^{17}O NMR, the four signals are easily observed at -11°C and a two-step exchange process averages all the sites, producing a single line at 108°C .

^{17}O NMR has been used to measure the rate of oxygen exchange in aldehydes and ketones,⁷⁷ cobaloximes,⁷⁸ and the periodate–water system.⁷⁹ It is possible to measure either the decay of a signal from a group enriched in ^{17}O or the growth of a signal that is undergoing exchange with ^{17}O labeled water.³

A substantial number of publications has been concerned primarily with studies of the hydration of ions in solution. The ^{17}O chemical shift of water molecules bound to Al^{3+} was found to be about 11 ppm to high frequency. Temperature dependence studies and lineshape analysis yielded the ^{17}O nuclear relaxation rates of the bound and free water molecules, the coordination number, and the rates of exchange between the bound and free water.⁸⁰ In addition, the thermodynamic parameters for activation characterizing the exchange reaction can be obtained. In cases where the chemical shift between ‘bound’ and ‘free’ water molecules is small, leading to overlapping of resonances, the resonance of the ‘free’ molecule can be shifted by adding small amounts of a paramagnetic salt.

Estimates of 4, 6, and 6 for the hydration numbers of $\text{Be}(\text{II})$, $\text{Al}(\text{III})$, and $\text{Ga}(\text{III})$ were obtained from area measurements. An alternative method of determining hydration numbers, by evaluating the magnitude of the shift of the water resonances caused by the dissolved paramagnetic ion, has also been suggested.⁸⁰

There is an extensive literature on ^{17}O NMR studies of the exchange rates of water molecules bound to paramagnetic ions.^{81–84} In this case there is a much greater chance of observing separate resonances from ^{17}O nuclei in ‘bound’ water molecules in the solvation shells of paramagnetic cations than in the corresponding diamagnetic cations. The magnitudes and temperature dependences of the linewidths (or relaxation time measurements) of the ‘bound’ and ‘free’ resonances, and the chemical shift separations between these resonances, can in principle be used to derive information about the hyperfine splitting constant, a_N , the rate of the solvent interchange process, T_e , and the solvation number. However, because the shifted resonance of the solvated water molecules is also often very broad, it is rarely possible in practice to derive the hydration number of the paramagnetic cation from straightforward area measurements. In such cases the hydration numbers may be obtained by using the theory developed by Swift and Connick⁸⁵ who investigated a variety of systems. This type of work and the chemical significance of the results have been reviewed (see *Paramagnetic Relaxation in Solution*).⁸⁶

4.2 ^{17}O NMR and Torsion Angle Effects

^{17}O NMR spectroscopy is a powerful method for detecting steric effects in molecules in which the steric interactions are characterized by the rotation of functional groups about single bonds to relieve van der Waals interactions or in rigid systems in which the steric interactions are partially accommodated by bond angle and bond length distortions.⁸⁷ ^{17}O deshielding is expected when the rotation leads to greater double bond character or reduced electron density on oxygen (e.g. in an isolated carbonyl group). Shielding, however, is observed in the situation in which the carbonyl group assumes more single bond character or increased density on the oxygen atom. Studies of such steric effects have been done on aromatic and heteroaromatic nitro compounds, aryl ketones, aldehydes and 1,2-diketones, aromatic carboxylic acids, esters and amides.^{88–91} For nitro aromatic compounds, a quantitative relationship was established between $\delta(^{17}\text{O})$ of the nitro group and the torsional angle between the aromatic ring and the nitro group (Figure 4). It appears that the solid state conformational preference, and thus the angle, is in remarkably good agreement with the average angle determined in the solution state.

4.3 Hydrogen-Bonding Effects (see *Hydrogen Bonding*)

The use of ^{17}O NMR appears to be especially promising for studying hydrogen-bonding interactions, because of the large chemical shift range of the oxygen nucleus.^{92–94} The dominance of intramolecular hydrogen-bonding effects over substituent effects has been clearly demonstrated in acetophenones, benzaldehydes, and hydroxynaphthoquinones.^{32,95} In

Figure 4 Plot of the torsion angles (X-ray) between aromatic rings and nitro groups versus ^{17}O chemical shift data.⁸⁷ (Reproduced by permission of CRC Press, Inc., from D. W. Boykin and A. L. Baumstark, in ' ^{17}O NMR Spectroscopy in Organic Chemistry', ed. D. W. Boykin, 1991, Chap. 3)

amides and peptides,^{10, 93, 96–100} both long-range dipole–dipole interactions and specific hydrogen bonds at the amide oxygen atom induce significant and specific shielding of the ^{17}O nucleus. Thus the overall chemical shift change between an amide oxygen atom in the absence of hydrogen-bonding interactions in vacuum and one that is fully hydrated in aqueous solution is, very probably, over 95 ppm. There is a linear correlation between $\delta(^{17}\text{O})$ and $\nu(\text{CO})$, the infrared (IR) amide I stretching vibration, for different solvents which have varying dielectric constants and solvation abilities.¹⁰⁰ This demonstrates that both IR and ^{17}O NMR spectroscopy appear to be reflecting a similar type of electronic perturbation, i.e. hydrogen bonding and dipole–dipole solute–solvent interactions. Further studies include investigations of the hydration and intra- and intermolecular hydrogen bonding of the *cis/trans* peptide oxygen atoms in AcYOH and AcYNHMe (Y = Pro or Sar)^{13, 98} (Figure 1), protected dipeptides,⁹⁹ and peptide hormones.^{101–103}

4.4 Oxygen Bonded to Transition Elements (Polyoxometalates)

^{17}O NMR has been employed frequently in stereochemical studies of polynuclear, anionic oxo complexes (polyoxoanions) of the early transition elements in a variety of oxidation states.^{104–108} In spite of their structural complexity, these polyoxoanions often yield well resolved ^{17}O NMR spectra, since large chemical shifts are observed and samples may often be observed at elevated temperatures in nonviscous solvents. Furthermore, ^{17}O enrichment is easily obtained. A representative example is the $[\text{V}_{10}\text{O}_{28}]^{6-}$ species, the structure and spectrum of which are shown in Figure 5. Exchange of oxygen atoms in the complex ion with those of H_2^{17}O in aqueous solution showed that all the different oxygen sites could be identified separately by their shieldings. If an oxygen atom attached to n vanadium atoms is designated as OV_n , then the observed chemical shifts are: $\text{OV} \simeq 1150$; OV_2 (three different sites) $\simeq 900, 790$ and 760 ; $\text{OV}_3 \simeq 390$; and $\text{OV}_4 \simeq 65$ ppm. It can be seen that there is a systematic reduction in $\delta(^{17}\text{O})$ with an increase in the number of vanadium atoms to which the oxygen atom is bound. Other complex anions of the formula $[\text{M}_6\text{O}_{19}]^{n-}$, where M = Mo ($n = 2$), Nb

Figure 5 (a) The D_{2h} symmetrized structure of $\text{V}_{10}\text{O}_{28}^{6-}$. Small filled circles represent vanadium atoms and large open circles represent oxygen atoms. One member of each symmetry-equivalent set of atoms is labeled. (b–e) ^{17}O NMR spectra at 13.5 MHz of $\text{V}_{10}\text{O}_{28}^{6-}$ in H_2O . All spectra were measured at 25°C with total vanadium concentrations of 1.5–1.8 M. The asterisk labels the metavanadate resonance. (Adapted by permission of The American Chemical Society from W. G. Klemperer and W. Shum, *J. Am. Chem. Soc.*, 1977, **99**, 3544)

($n = 8$), or Ta ($n = 8$), show the same qualitative regularities in shielding, with $\text{OM} > \text{OM}_2 > \text{OM}_6$. These regularities have been interpreted as a correlation between increasing chemical shift and increasing π bonding from the metal to the oxygen in different sites. The regularities persist in the ^{17}O spectra of a variety of more complex anions of lower symmetry in which other metals or nonmetals are substituted within an $[\text{M}_x\text{O}_y]^{n-}$ framework. It should be noted that the resonances of oxygen nuclei in the highly symmetrical environments of the complex anions, e.g. OM_4 or OM_6 , are relatively sharp. This is to be expected because the field gradient at these positions will be zero or very small; hence the normally dominant quadrupolar relaxation mechanism will be very weak and the relaxation times correspondingly long.

4.5 Heme Proteins and Model Compounds—Substrate Binding to Enzymes

The ^{17}O NMR spectra of several heme model compounds in solution have been reported.^{11, 109–111} Two signals at about

Figure 6 ^{17}O NMR spectra (54.2 MHz) of the oxygenated compounds **a** (---) and **b** (—) with a preacquisition delay time $\Delta t = 50 \mu s$ and recorded in two steps with the carrier frequency on the absorption resonances. Maximum concentration $\approx 10^{-2} M$ in toluene solution. Concentration of 1,2-dimethylimidazole (1,2-Me₂Im) $\approx 5 \cdot 10^{-1} M$, $T = 297 K$, NS = 1 080 000 (LB = 1 kHz) and 350 000 (LB = 500 Hz) for the high- and low-frequency resonances, respectively. The arrow denotes the region of the resonance position of the terminal oxygen atom of the picket-fence porphyrin model, with excess 1-MeIm, and ether models in which no hydrogen bonding interactions are expected. (Adapted by permission of the Royal Society of Chemistry from I. P. Gerothanassis, B. Look, and M. Momenteau, *J. Chem. Soc., Chem. Commun.*, 1992, 598)

1750 and 2500 ppm were observed for the FeO₂ linkage (Figure 6). The data were interpreted as ruling out sideways triangular bonding in favor of an end-on angular bonding arrangement. The data were explained in terms of bonding models in which the electrons of the FeO₂ moiety are totally paired.

Analysis of the ^{17}O relaxation and chemical shift data of $C^{17}O$ ligated hemoproteins has provided information on both the structural and the dynamic properties of the heme group.^{49,75,112} Peroxidases are heme proteins with molecular weights of about 40–42 kDa that catalyze oxidations by hydrogen peroxide. They contain iron-protoporphyrin IX as a noncovalently bound prosthetic group. The ^{17}O NMR spectra of CO-horseradish peroxidase isoenzyme C (Figure 7) indicate a single hemoprotein $C^{17}O$ signal (at 358.3 ppm) below pH 10 and two separate signals at pH 10.5. The new signal, which was assigned with the alkaline form of CO-horseradish peroxidase isozyme C, is broader and at about 7 ppm to high frequency relative to that of the acidic form. A similar pH-dependent relationship of the chemical shift and linewidth was observed for CO-horseradish peroxidase isozyme A and CO-horseradish peroxidase isozyme C. It was concluded that CO-horseradish peroxidase isozyme C undergoes a transition between the acidic and alkaline forms.¹¹² However, unlike the case of CO-horseradish peroxidase isozyme A, the transition is slow on the NMR timescale (see *Oxygen-17 NMR: Applications in Biochemistry*).

4.6 Hydration of Proteins: Water Orientation in Lyotropic Phases and Bilayers

Water plays a fundamental role in the conformation and activity of biological macromolecules (see *Protein Hydration*).

Figure 7 Oxygen-17 NMR spectra of CO-horseradish peroxidase isozyme C (CO-HRPC); concentration, 1 mM in 50 mM phosphate buffer at 11.7 T; NS = 50 000–250 000, recycle time 100–150 ms, pulse width $38 \mu s$, LB = 100 Hz. A, B, and CO_{aq} denote the acidic form of CO-HRPC, the alkaline form of CO-HRPC, and free CO in solution, respectively. (Reprinted by permission of The American Society for Biochemistry and Molecular Biology from H. C. Lee, K. Cummings, K. Hall, L. P. Hager, and E. Oldfield, *J. Biol. Chem.*, 1988, **263**, 16 118)

^{17}O NMR studies have several advantages compared with 1H and 2H NMR for protein hydration:

1. The relaxation effect is large, permitting studies at low protein concentrations.
2. The ^{17}O relaxation in water is generally dominated by the quadrupolar mechanism.^{113,114} The intramolecular origin of the electric field gradient makes the quadrupolar interaction virtually independent of the molecular environment.
3. The ^{17}O relaxation is not affected by proton (or deuteron) exchange with protic residues in the protein. Only T_2 can be affected by exchange within a narrow pH range near neutrality.
4. Cross relaxation that contributes to 1H relaxation is unimportant for ^{17}O .^{115,116}

Variable field T_1 and T_2 relaxation time measurements of several proteins¹¹⁷ were interpreted in terms of two layers of

hydration having a reorientational correlation time of about 20 ps (about eight times slower than that of bulk water and independent of the nature of the protein). This rapid local motion has a small anisotropic component (corresponding to an order parameter of 0.06) which is averaged out by protein reorientation with a correlation time of the order of 10 ns.

Water molecules are important constituents of lyotropic phases and bilayers. In this case the molecular motions are strongly anisotropic and the quadrupolar interaction is not averaged out to zero and may be measured when it is small compared with the Zeeman interaction. Ordering of a water molecule results in a quadrupolar splitting which is related to the order parameter. It has been shown that important dynamic information can be obtained from ^{17}O linewidth data which complement the ordering results from ^2H NMR.¹¹⁸ (see *Amphiphilic Liquid Crystalline Samples: Nuclear Spin Relaxation* and *Liquid Crystalline Samples: Structure of Nonrigid Molecules*).

4.7 The Solid State

Under conditions of magic angle spinning (MAS) (see *Magic Angle Spinning*), the $(\frac{1}{2}, -\frac{1}{2})$ transition of quadrupolar nuclei with nonintegral spin does not depend on first-order quadrupolar interactions or on the effects of θ (the angle between B_0 and q_{zz}). The powder bandshapes depend upon second-order quadrupolar effects which do not eliminate the possibility of obtaining meaningful NMR spectra. In this case operation at very high magnetic fields will generally be most advantageous since the maximum second-order quadrupolar linewidth of the $(\frac{1}{2}, -\frac{1}{2})$ transition decreases linearly with the magnetic field.¹¹⁹ Typical results are those obtained for a range of oxides, oxyanions and high temperature oxide superconductors.^{120–122} For fosterite (Mg_2SiO_4), in which three crystallographically distinct oxygen sites were partly resolved, it was possible to determine the chemical shifts (61, 62, and 47 ppm), the quadrupole coupling constants (2.35, 2.35, and 2.7 MHz), and the electric field gradient tensor asymmetry parameters (0.2, 1.0, and 0.3) associated with each. From similar studies of silicate minerals and other compounds it was found that the χ values are related to the percentage ionic character of the bonds to oxygen.¹²⁰ It has also been found that VAS can be advantageous, especially for removing resonances arising from transitions other than $(\frac{1}{2}, -\frac{1}{2})$ (see *Variable Angle Sample Spinning*). Furthermore, it has been demonstrated that ^{17}O spins can be polarized by the ^1H spin system, as is done for ^{13}C in CP MAS.¹²³

^{17}O NMR studies on single crystals have the advantage, compared with studies on powders, that the complete principal components of the nuclear quadrupolar coupling constant and shielding tensors can be obtained and their orientation relative to the local molecular symmetry can be determined.¹²⁴

1 INTRODUCTION

The statistical structure of linear polymers in dilute or semi-dilute solution, whose main characteristic is its fractal dimension, has been the subject of extensive studies in modern times, on both theoretical and experimental levels. The interest it raised in physics is because, as a branch of theoretical statistical physics, it is amenable to extremely clean and elaborate treatments making use of sophisticated mathematical techniques.^{1–3} It also offered an ample field for experimentation. One of the most sensitive and most extensively used tools for these polymer studies is small angle neutron scattering (SANS), which yields the Fourier transform of the average space correlation of pairs of nuclei. This kind of approach corresponds to an exploration of the reciprocal or k space of the polymers.

NMR has been largely absent so far from this class of problems; there are a few exceptions. The numerous NMR studies of polymers (for example, see the articles on polymers in the *Encyclopedia of NMR*) are centered on different properties of these systems. The first exception is the use of dynamic polarization in partly protonated and partly deuterated polymers in solid glassy solutions, in connection with SANS, whose unique quality is that it enables one to change continuously the neutron scattering *amplitude* by the polarized nuclei, an enormous advantage for disentangling the various contributions to the neutron scattered intensity.^{4,5} The second exception is mentioned later.

The approach described is to study the influence of the average polymer structure on the characteristics of spin-lattice relaxation.^{6,7} More precisely, we study nuclear relaxation without spin diffusion, under the influence of paramagnetic centers, in polymers in solution in a solid glass. The advantage of this is that, since the various spins relax independently of one another, we can see the sum of the individual magnetization evolutions, which is an additive phenomenon. Therefore, the bulk evolution under relaxation of the NMR signal reflects the statistical structural distribution of the polymers. This statistical sensitivity to the environment is well known in ordinary 3D solids, as is discussed later.

Several conditions are required for this study of polymers.

1. The polymers must be static, that is embedded in a solid, which must be a glass, so as not to strain their structure with respect to that in liquid solution. This constraint does not exist in standard SANS, because the high energy of the neutrons (by comparison with the kinetic energy of the atoms or molecules), the polymer motions in a liquid are completely unnoticed by them: for neutrons, a liquid is as 'static' as a solid.
2. Only the nuclei of the polymer must have a large nuclear moment, and not those of the solvent, to investigate the structure of the polymer itself, without contributing to relaxation from the solvent nuclei. The obvious choice is that of protonated polymers in a deuterated solvent. The latter must be a good solvent down to the glassy transition, so as to preserve the structure of the polymers and to avoid their segregation.
3. The only sufficiently tractable case is that when the paramagnetic centers are located on the polymer itself, and not in the solvent. For usual protonated polymers, the choice is most often limited to nitroso radicals. Furthermore, these radicals must be easily grafted to the polymers.
4. The electronic relaxation time, which in practice is the correlation time for the nuclear relaxation, must have an adequate value which imposes that the sample temperature be in the liquid nitrogen range.
5. In order for the time required for nuclear relaxation to remain within a reasonable range, it is necessary for the concentration of paramagnetic centers relative to the relaxing nuclei not to be too small. In the case when only one center is grafted on each polymer, this imposes in practice a maximum size for the polymers.

An experiment of diffusion-free nuclear relaxation by impurities on fractal systems has already been done. (This is the second exception to non-NMR studies to polymer-like fractal structure.) It was performed on ²⁹Si by Devreux et al. in silica aerogels.⁸ These have a network structure characterized by a fractal dimension D slightly in excess of two. Using an angular average for the individual relaxation rates, the authors showed that the initial variation of the nuclear polarization was proportional to $t^{D/6}$. This was tentatively extended to an exponential law of the form

$$\langle p(t) - p_{eq} \rangle \propto \exp \left[- \left(\frac{t}{\tau_1} \right)^{D/6} \right] \quad (1)$$

Experimentally, spin diffusion was quenched by averaging the dipole-dipole interactions between ²⁹Si nuclei to zero by

sample spinning at the magic angle $\theta = \arccos(1/\sqrt{3})$, and the results correlated well with theory.

In this article, diffusion-free relaxation is investigated in the absence of irradiation, or under off-resonance nuclear irradiation as a function of the angle between the effective field in the rotating frame and the steady field. The measurements concern both the rate of evolution of the bulk nuclear magnetization along the effective field and its steady-state limit. Two types of systems were studied: the paramagnetic centers are grafted at random positions on the polymer; or only one center is grafted on each polymer in a well defined position, usually at one end. For the results to be interpretable, the polymers are monodispersed.

The article is organized in the following sections:

1. A review of the basic facts of nuclear relaxation by dipolar coupling with paramagnetic centers.
2. Description of the experimental procedure and its validation in a 3D solid.
3. Statistical properties of linear polymers in dilute or semi-dilute solution, as results from theory backed by neutron scattering experiments.
4. Description of the investigation of several systems and comparison with theory.
5. Discussion of the problem of spin ‘diffusion’.
6. Conclusion and perspectives.

2 BASICS OF RELAXATION BY FIXED PARAMAGNETIC CENTERS

This section is essentially a short summary of well-known facts of NMR.

It has been known since 1949⁹ that in insulating solids, the relaxation of nuclear spins 1/2 proceeds from the combination of two processes: direct relaxation by paramagnetic centers, usually present at low concentration, combined with homogenization of the polarization throughout the sample via dipolar-induced flip-flops among the nuclear spins, described by a diffusion equation, leading to an exponential decay of the bulk polarization. The situation is changed when the flip-flops are quenched by a decrease of the effective dipolar interactions, for instance through a strong off-resonance rf irradiation so as to orient the effective field in the rotating frame at the magic angle from the external field.^{10–12} Then, one observes the independent direct relaxation of the individual spins. Even when the dipolar interactions are not completely averaged to zero, it is generally possible to observe the diffusion-free relaxation at the beginning of the nuclear magnetization evolution. These are the conditions used in the present study.

2.1 Nuclear Spins Subjected to Strong rf Irradiation

A system of nuclear spins I in a steady magnetic field is subjected to a strong rf field B_1 rotating at a frequency ω at a value $\Delta = \omega_0 - \omega$ from the Larmor frequency. In a frame rotating at frequency ω , the spins are subjected to a steady magnetic field B_{eff} of components $-\Delta/\gamma$ and B_1 along the axes Oz and Ox respectively, that is oriented along an axis OZ tilted by the angle $\theta = \arctan(B_1/(-\Delta/\gamma))$ Oz (see Figure 1). The effective Hamiltonian has the form

$$\mathcal{H}_{\text{eff}} = \Delta I_z + \omega_1 I_x + \mathcal{H}'_{Dz} = \Omega I_Z + \mathcal{H}'_{Dz} \quad (2)$$

Figure 1 Effective field in the rotating frame under off-resonance irradiation

where, in the last term on the right-hand side, we express the effective Zeeman interaction with respect to the orientation OZ of the effective field (see Figure 1), and $\mathcal{H}'_{Dz}$ is the secular dipolar interaction in the rotating frame, commuting with the operator I_z .

If as we assume, the effective Zeeman interaction is much larger than the dipolar one, the latter has to be truncated so as to retain only its part which commutes with the effective Zeeman interaction, that is with the spin operator I_z . This is done by rewriting the dipolar Hamiltonian in the system of axes $OXYZ$ and rejecting all terms which differ from $\mathcal{H}'_{Dz}$, of the same form as $\mathcal{H}'_{Dz}$ but expressed in the new system of axes. The corresponding coefficient is equal to $1/2(3 \cos^2 \theta - 1)$, a standard result recalled in Tabti et al. and discussed at length in Blumberg, Tse and Hartmann, and Lin and Hartmann.^{7,9–11} It is easily recovered by an elementary calculation. The new effective dipolar interaction is then

$$\mathcal{H}''_{Dz} = \frac{1}{2}(3 \cos^2 \theta - 1) \mathcal{H}'_{Dz} \quad (3)$$

The magnitude $1/2|3 \cos^2 \theta - 1|$ can be modified at will within limits by adjusting the angle θ . If we use a second rotating frame, of frequency Ω around OZ , the evolution of the spin system is governed by the effective dipolar interaction $\mathcal{H}''_{Dz}$.

2.2 Local Nuclear Relaxation by a Paramagnetic Center

We consider a paramagnetic spin S at the origin and a nuclear spin I with polar coordinates (r, α, β) . Under rf irradiation, the orientation of the spin I is locked along the

direction OZ of its effective field in the rotating frame. Its relaxation through its dipolar coupling with the spin S is calculated through a combination of the methods of Abragam and Tomita.^{13,14} The spin S components fluctuate randomly under the effect of its own spin-lattice relaxation, with a longitudinal time T_{1e} . We assume that $\omega_e T_{1e} \gg 1$, where ω_e is the electronic Larmor frequency, so that the only effective S spin component contributing to the nuclear relaxation is S_z , and the correlation time of the random $I - S$ coupling is $\tau_c = T_{1e}$. The relaxing Hamiltonian is of the form

$$\mathcal{H}_{IS}(t) = AS_z(t)I_z + \{BS_z(t)[I_x + iI_y] + h.c.\} \quad (4)$$

with

$$\begin{aligned} A &= \frac{\gamma_I \gamma_S \hbar}{r^6} (1 - 3 \cos^2 \alpha), \\ B &= -\frac{3}{2} \frac{\gamma_I \gamma_S \hbar}{r^6} \sin \alpha \cos \alpha \exp(-i\beta) \end{aligned} \quad (5)$$

In the hypothesis, often realistic, that $\Omega\tau_c \ll 1$, the relaxation evolution of the component I_Z is a weighted average of those of I_z and I_x . It corresponds to the equation

$$\frac{d}{dt} \langle I_Z \rangle = -\frac{1}{T_1} [\langle I_Z \rangle - \langle I_Z \rangle_{st}] \quad (6)$$

where a standard relaxation calculation yields

$$\frac{1}{T_1} = \frac{S(S+1)}{3} [A^2 \sin^2 \theta J(0) + 2|B|^2 (1 + \cos^2 \theta) J(\omega)] \quad (7)$$

The spectral densities are of the usual form

$$J(\omega) = \frac{\tau_c}{1 + \omega^2 \tau_c^2} \quad (8)$$

The relaxation rate, equation (7), can be written under the general form

$$\frac{1}{T_1}(\alpha, r) = \frac{C(\alpha)}{r^6} \quad (9)$$

where $C(\alpha)$, which depends on the angle α between the direction of the vector SI and the external field through the square of its sine or cosine, also depends on the angle θ between effective and external fields.

Equation (7) agrees with the relaxation rates derived for the z and x components

$$\frac{1}{T_{1z}} = \frac{1}{T_1}(\theta = 0); \quad \frac{1}{T_{1x}} = \frac{1}{T_1}(\theta = 90^\circ) \quad (10)$$

As for the steady-state value towards which $\langle I_Z \rangle$ evolves, it corresponds to a compromise between the tendency of $\langle I_z \rangle$ to evolve towards the thermal equilibrium value I_0 and that of $\langle I_x \rangle$ to evolve towards 0. The result is

$$\langle I_Z \rangle_{st} = I_0 \frac{\cos \theta}{\cos^2 \theta + (T_{1z}/T_{1x}) \sin^2 \theta} \quad (11)$$

All these results can be cleanly derived, and they can be extended to the case when the condition $\Omega\tau_c \ll 1$ is not fulfilled: one must simply replace $J(0)$ with $J(\Omega)$ in equation (7).¹⁵

2.3 The Steady-State Polarization in a Bulk Sample

The steady-state polarization for a single spin I given in equation (11) depends on the polar angle α through the dependence of T_{1z} and T_{1x} on this angle. In a bulk sample, flip-flop processes, when given enough time to take place, homogenize these steady-state values. The final result is a bulk steady-state polarization of the form

$$\frac{\langle I_Z \rangle_{st}}{I_0} = \frac{\cos \theta}{\cos^2 \theta + f(\tau_c) \sin^2 \theta}, \quad (12)$$

where the factor $f(\tau_c)$ is equal to a ratio of average relaxation rates

$$f(\tau_c) = \left(\frac{1}{T_{1x}} \right) / \left(\frac{1}{T_{1z}} \right) \quad (13)$$

Its formal expression is

$$f(\tau_c) = \frac{1}{2} + \frac{2}{3} \omega^2 \tau_c^2 \quad (14)$$

The importance of equations (12) and (14) is that by merely measuring the steady-state NMR signal as a function of the angle θ between effective and external field, one obtains an accurate determination of the correlation time τ_c , that is the spin-lattice relaxation time of the paramagnetic centers, irrespective of whether the EPR linewidth is homogeneous or inhomogeneously broadened. This very general result, independent of the structure of the system, may be considered a by-product of some value of the present study.

2.4 Diffusion-Free Relaxation in a Bulk Sample

We give here but an outline of the way of handling the problem of determining the shape of the relaxation evolution of the bulk polarization towards its steady-state value.

The problem is essentially of statistical nature. The magnetization of each individual nuclear spin evolves according to the equation

$$\langle I_Z^i \rangle(t) = \langle I_Z^i \rangle_{st} + (\langle I_Z^i \rangle(0) - \langle I_Z^i \rangle_{st}) \exp\left(-\frac{t}{T_1^i}\right) \quad (15)$$

One must sum over all spins, or else consider a 'typical' spin and calculate its average evolution through the probability distribution of relaxation times and steady-state limits

$$\langle I_Z \rangle(t) = \overline{\langle I_Z \rangle_{st}} + \overline{\langle I_Z \rangle(0) \exp\left(-\frac{t}{T_1}\right)} - \overline{\langle I_Z \rangle_{st} \exp\left(-\frac{t}{T_1}\right)} \quad (16)$$

Where the overbar means a bulk statistical average, whereas the brackets correspond as usual to quantum-mechanical expectation values.

As a general rule, all initial magnetizations are equal, which is why the second average on the right-hand side of equation (16) is only on the time-dependent term. This average is relatively easy to calculate. This is not the case for the last joint average, because both the individual $\langle I_Z^i \rangle_{st}$ and T_1^i produced by a single paramagnetic center depend on the polar angle α . This is not too severe when the paramagnetic centers are distributed at random, because most spins will be relaxed by several centers, and the local $\langle I_Z^i \rangle_{st}$ will not differ much from the average. The problem might arise in the case of dilute polymers with only one center grafted on each, that is when

all nuclear spins are relaxed only by one center. However, in all cases studied so far, one always had $\omega\tau_c \gg 1$, so that except in a very small domain of angles α around the magic value, one has $T_{1z}^i/T_{1x}^i \gg 1$ and $\langle I_Z^i \rangle_{st}$ is small compared with $\langle I_Z \rangle(0)$, so that its exact value is of little importance over most of the evolution.

The methods used for calculating the average $\overline{\exp(-t/T_1^i)}$ will not be detailed here, and we will only give and briefly comment on the results for the various cases under study.

3 THE MODEL STRUCTURE OF LINEAR POLYMERS

Although the experimental study was made with finite and relatively short polymers, we describe them by the same model as that derived theoretically in the limit of very long polymers.¹⁻³

Linear polymers in dilute solution, that is at a concentration c smaller than the overlap concentration c^* , to be defined later, are independent of each other. Being flexible, they can be present under a variety of configurations. One can define a mean statistical structure by performing an average of all possible configurations. This structure is of spherical symmetry and is characterized by a fractal dimension D . What is meant by this is that around any point of the polymer the number of monomers (or the number of nuclei) present in a sphere of radius r is of the form

$$n_n(r) = \lambda r^D \quad (17)$$

from which we can define an average nuclear density $\rho(r)$ through

$$\frac{d}{dr} n_n(r) = D\lambda r^{D-1} = 4\pi r^2 \rho(r) \quad (18)$$

that is

$$\rho(r) = \frac{1}{4\pi} D\lambda r^{D-3} \quad (19)$$

For linear polymers in solution in a good solvent, this dimension is equal to $D = 1.7$.

We define an effective radius R as that of a sphere that contains all the nuclei N_n of the polymer

$$R = \left(\frac{N_n}{\lambda} \right)^{1/D} \quad (20)$$

and we assume that the density $\rho(r)$ is of the form shown in equation (19) up to $r = R$ and vanishes at larger values. This is obviously an oversimplification, but it will turn out to be convenient.

Among other kinds of radii used in the study of polymers there is the so-called gyration radius R_G defined through

$$R_G^2 = \frac{1}{2(N+1)^2} \sum_{i,j} (\mathbf{r}_i - \mathbf{r}_j)^2 \quad (21)$$

where N is the number of monomers and $\mathbf{r}_i - \mathbf{r}_j$ is the vector joining the monomers i and j . Its value is experimentally derived by small angle neutron scattering.

Another radius, called R_F , equal to the r.m.s. end-to-end distance of the polymer, is theoretically related to R_G through

$R_F = 2.51 R_G$. The vector R of equation (20) is likely to be of an order of magnitude that is similar to these radii.

Among several different definitions of the polymer overlap concentration c^* , the simplest one in the present case is

$$4\pi R^3 c^* = 1 \quad (22)$$

The polymers are said to be in semi-dilute solution when their concentration c is somewhat larger than the concentration c^* , so that they partly overlap. In this case, all points of the polymer are still statistically equivalent: in a sphere of radius ξ around a 'typical' point, the fractal dimension has the same value $D = 1.7$ as in dilute solution, and beyond this distance, the dimension is the same as that of the host medium, that is $D = d = 3$.

The knowledge of the fractal dimension is sufficient to determine the shape of the signal evolution at short time, when only those nuclei close to a paramagnetic center are substantially relaxed. The centers are at low concentration, so that these nuclei are only relaxed by one impurity. The centers being grafted on the polymers, the density of nuclei around them corresponds to the same fractal dimension as the polymers. Starting from zero initial saturation, the evolution of the nuclei at a polar angle α with respect to the center is approximately of the form

$$\langle I_Z \rangle(\alpha; t) \propto \langle I_Z \rangle_{st} \int_{r=b_0}^{\infty} \left[1 - \exp\left(\frac{-C(\alpha)t}{r^6}\right) \right] d(r^D) \quad (23)$$

where b_0 is the barrier within which the nuclei, of frequency shifted by the average electronic dipolar field, are not observed. For $ct/b_0^6 \gg 1$, and by using the notation

$$x = \frac{C(\alpha)t}{r^6} \quad (24)$$

we obtain a result of the form

$$\langle I_Z \rangle(\alpha; t) = \langle I_Z \rangle_{st} (1 - \zeta t^{D/6}) \quad (25)$$

This form remains true when integrating over the angle α . As for the complete form of the evolution, it requires a more elaborate calculation, and it depends on the distribution of the relaxing centers around the nuclei.

4 EXPERIMENTAL METHODS – VALIDATION ON A 3-D SYSTEM

4.1 Experimental Procedure

Within an electromagnet producing a horizontal field, the sample is cooled in a cryostat by flowing cooled nitrogen gas around it. A resistor is used to adjust the gas temperature to within 0.5 K between liquid nitrogen and room temperatures. The sample temperature was as a rule around 100 K. The pulsed spectrometer operates at a frequency around 100 MHz. The field B_1 is of the order of 1 mT, rotating component, that is much larger than the local field of the compounds used, about 0.2 to 0.3 mT. The rf field can be applied up to 9 s without problems.

The measuring sequence goes as follows: the thermal equilibrium magnetization is spin-locked along the direction OZ of the effective field; after an evolution time t , the

magnetization is as a rule realigned with the steady field and then subjected to a $\pi/2$ pulse, and the FID amplitude is measured. The manipulations of the magnetization directions are performed by appropriate pulses and evolution periods.

4.2 Validation on a 3-D Solid: Protonated *O*-Terphenyl

The sample was protonated *o*-terphenyl (OTP) doped with the radical 4-hydroxyl TEMPO (tetramethyl-2,2,6,6 piperidinol-4 oxyle-1) at a concentration of $4.3 \times 10^{19} \text{ cm}^{-3}$. It was degassed and cooled at 143 K. The centers were then randomly distributed. The relaxation time without rf irradiation was 0.78 s.

For randomly distributed relaxing centers, the theoretical evolution of the nuclear magnetization is an exponential function of $\sqrt{t}$, in accordance with the initial law (see equation (25)).^{6,7,10-12,16}

$$\langle I_Z \rangle(t) - \langle I_Z \rangle_{st} = (\langle I_Z \rangle(0) - \langle I_Z \rangle_{st}) \exp \left[- \left(\frac{t}{\tau_1} \right)^{1/2} \right] \quad (26)$$

This law is deduced from a statistical analysis of the paramagnetic center random distribution, and from the fact that, when 'seeing' several paramagnetic centers, the relaxation rate of a given nucleus is the sum of those due to the individual centers.

The expressions for the relaxation rates and steady-state magnetizations as a function of the angle θ between external and effective fields are given in Tabti and Tabti et al. with only two adjustable parameters: the correlation time $\tau_c = T_{1e}$ and the concentration of the relaxing centers. The variation of the steady-state reduced magnetization as a function of the angle θ is shown in Figure 2, together with a best-fit theoretical curve corresponding to

$$\tau_c = 6.5 \pm 0.2 \times 10^{-8} \text{ s}. \quad (27)$$

Figure 2 Reduced steady-state magnetization as a function of the angle θ between external and effective field in protonated OTP, together with a best-fit theoretical curve with $\tau_c = 6.5 \pm 0.2 \times 10^{-8} \text{ s}$

As for the time-decaying part, it consists of three parts: an initial plateau due to the non-observation of the nuclei close to the centers, an exponential function of $\sqrt{t}$ of the form shown in equation (26), and a final exponential decay as a function of t , when spin diffusion becomes faster than direct relaxation. For the part evolving according to equation (26), the variation of $\tau_{1/2}$ as a function of the angle θ is shown in Figure 3 together with a best-fit curve.

Using the preceding value of τ_c , it yields the concentration of paramagnetic centers

$$N_p = 6.4 \pm 0.1 \times 10^{19} \text{ cm}^{-3} \quad (28)$$

The fact that this concentration is larger than the nominal one is attributed to the evaporation of some OTP during the degassing process.

These results constitute a validation of the experimental procedure, and provide in addition two pieces of information: the electronic relaxation time and the concentration of the centers.

5 RESULTS FOR POLYMER SOLUTIONS

5.1 Polymers with Randomly Distributed Paramagnetic Centers

The only system studied consisted of poly 2-vinyl pyridine (P_2VP) of average molecular mass $2 \times 10^5 \text{ g mole}^{-1}$ on which paramagnetic vanadyl sulphate $VOSO_4$ was grafted at random. It was in semi-dilute solution ($c = 0.05 \text{ g cm}^{-3}$) in deuterated glycerol. This system, studied only for illustration purposes, did not use rf irradiation, and it concerns only the longitudinal relaxation.

For polymers of fractal dimension D with random relaxing centers grafted on them, a statistical calculation analogous to that use for 3-D solids yields an evolution law of the magnetization of the form

$$\langle I_Z \rangle(t) - \langle I_Z \rangle_{st} = (\langle I_Z \rangle(0) - \langle I_Z \rangle_{st}) \exp \left[- \left(\frac{t}{\tau_1} \right)^{D/6} \right] \quad (29)$$

Figure 3 Variation of $\tau_1^{1/2}$ as a function of the angle θ in protonated OTP, together with a best-fit curve with $N_p = 6.4 \pm 0.1 \times 10^{19} \text{ cm}^{-3}$

Figure 4 Longitudinal relaxation curve for a semi-dilute solution of P₂VP. The initial decay, an exponential function of $t^{D/6} = t^{0.28}$ (solid line), is followed by an exponential function of time (dashed curve)

The experimental magnetization evolution, shown in Figure 4, does indeed display such an initial behavior, followed at longer times by an exponential variation, when spin diffusion takes over.

5.2 Polymers with One Paramagnetic Center at One End

The situation for relaxation is markedly different from the preceding one. Indeed, for dilute solution, the relaxation of the nuclei of a polymer is essentially produced by only one center, the one located on the polymer. What the statistical calculation predicts is that over a substantial range, the evolution of the magnetization is a *linear* function of $t^{D/6}$

$$\langle I_Z \rangle(t) - \langle I_Z \rangle_{st} = (\langle I_Z \rangle(0) - \langle I_Z \rangle_{st}) \left(1 - \left(\frac{t}{\tau_1} \right)^{D/6} \right) \quad (30)$$

The theoretical curve for the model used is shown in Figure 5, together with an exponential of equal initial slope for comparison. The expected variation for the polymer is indeed linear from initial value 1 down to about 0.4–0.3. We come now to the experimental investigation.

The polymer used is polystyrene of molecular mass of about 8000 (i.e., corresponding to 80 monomers) at the end of which was grafted the radical tetramethyl-2,2,5,5 carboxy-3 pyrrolinyl oxyle-1 (commercial name 3-carboxy PROXYL), diluted in deuterated OTP and then cooled to 120 K. The overlap concentration c^* is estimated to about 0.25 g cm^{-3} . Experiments were performed on dilute and semi-dilute solutions.

From a study of the steady-state reduced polarization as a function of the angle θ , shown in Figure 6, the best-fit value for the correlation time is

$$\tau_c = 2.6 \pm 0.4 \times 10^{-8} \text{ s}. \quad (31)$$

Figure 5 Theoretical variation of the reduced magnetization as a function of $t^{0.28}$ in a dilute solution of polymers with one relaxation center at one end (solid curve). For comparison, the dashed curve is an exponential with the same initial slope

Figure 6 Dilute solution of polystyrene with one relaxing center at one end. Reduced steady-state magnetization as a function of the angle θ , together with a best-fit theoretical curve with $\tau_c = 2.5 \pm 0.4 \times 10^{-8} \text{ s}$

5.2.1 Dilute Solution

The polystyrene concentration was 0.05 g cm^{-3} . A typical evolution curve, for the magic angle $\theta = \arccos(1/\sqrt{3})$, is shown in Figure 7.

One observes indeed a linear variation, but down to about 0.1, that is beyond theoretical expectation. This may be due to the crude structure model used: a sudden drop of the nuclear concentration beyond R , or to the interaction with the other polymers. In the absence of any firm theoretical model for the concentration variation of the nuclear density at the largest

Figure 7 Dilute solution of polystyrene with one relaxing center at one end. Relaxation along an effective field at the magic angle from the external field. Linear reduced magnetization as a function of $t^{0.28}$

Figure 8 Semi-dilute solution of polystyrene with one relaxing center at one end, under irradiation at resonance. Linear reduced magnetization as a function of $t^{0.28}$

distances, we did not investigate this matter further. Knowing τ_c from the steady-state variation, it is possible to determine the radius R from the evolution with angle θ of the value of τ_1 in equation (30). The best fit value is:

$$R = 3.1 \pm 0.15 \text{ nm}, \quad (32)$$

to be compared with the neutron-scattering-measured value $R_G = 2.1 \text{ nm}$ and the corresponding $R_F = 5.2 \text{ nm}$. All three radii are indeed of the same order of magnitude.

5.2.2 Semi-dilute Solution

The same polystyrene polymers were used at a concentration of 0.30 g cm^{-3} , slightly above the overlap concentration $c^* = 0.25 \text{ g cm}^{-3}$. The experimental relaxation evolution is shown in Figures 8 and 9 for $\theta = 90^\circ$. In Figure 8, the signal is plotted as a function of $t^{D/6}$ and it exhibits the same linear variation as for the dilute solution. In Figure 9, the signal is plotted as a function of $t^{1/2}$ on a logarithmic scale, showing that in the end the signal varies as an exponential function of $\sqrt{t}$. All these features agree qualitatively with the model of semi-dilute solutions of polymers: a region of fractal dimension 1.7 with at most one impurity, surrounded by a homogeneous medium with randomly distributed paramagnetic centers.

6 THE PROBLEM OF SPIN DIFFUSION

This topic, which is not directly connected with the NMR investigation of the polymer structure, will be given a schematic discussion only.

When the angle between the effective and external fields is different from the magic angle, i.e., when the effective secular dipolar interactions do not vanish, the end of evolution of the signal is an exponential function of time. This is brought

Figure 9 Same as Figure 8, but with different scales: Logarithm of the reduced magnetization as a function of $t^{1/2}$ (solid line), and its variation as a function of $t^{0.28}$ (dashed curve)

about by the homogenization of the polarization through flip-flop processes under the influence of the secular dipole-dipole interactions. In usual 3-D solids, this nuclear polarization transfer through space is tentatively described by a diffusion equation, and referred to as spin diffusion. All experimental results on nuclear relaxation by paramagnetic centers in non-conducting solids are in good agreement with this description.

Besides more or less complicated and approximate theoretical treatments of this problem, a particularly enlightening picture of spin-diffusion-induced exponential evolution is that of Blumberg. We summarize it for the so-called diffusion-limited case, in a spherical system of radius R with a relaxing center at the origin, and neglect the angular dependence of the

coefficient C , in equation (9), as well as that of the diffusion coefficient D . The time necessary for direct relaxation to reach the distance r is of the order of $t_r = r^6/C$, whereas the corresponding time for diffusion is of the order of $t_d = r^2/D$. Both times are equal at a distance

$$b \approx \left(\frac{C}{D}\right)^{1/4} \quad (33)$$

Up to this distance, relaxation acts independently on the nuclei, and beyond it diffusion homogenizes the polarization. The relaxation of this part is exponential, with a relaxation rate equal to the average of the individual rates. If ρ is the nuclear density, we obtain

$$\frac{1}{T_1} \approx \frac{C \int_b^R \rho r^{-4} dr}{\int_b^R \rho r^2 dr} \quad (34)$$

which, for a 3-D solid where the density is constant and for $b \ll R$, yields

$$\frac{1}{T_1} \approx \frac{C}{R^3 b^3} \quad (35)$$

a result equal, within a numerical factor of order unity, to that predicted by more sophisticated methods, and in agreement with experiment for randomly distributed centers at low concentration, with R equal to the average distance between centers. We can compare it with the time τ necessary for diffusion to travel the distance R

$$\tau \approx \frac{R^2}{D} \quad (36)$$

We obtain from equations (33) and (35)

$$\frac{\tau}{T_1} \approx \frac{(C/D)R^2}{R^3 b^3} \approx \frac{b}{R} \ll 1 \quad (37)$$

which validates the coherence of the model.

This approach is not adapted to dilute polymers of fractal dimension $D = 1.7$, for two reasons. First, and contrary to direct relaxation, it is hardly justified to use an ‘average’ polymer, since the dipolar-induced transport of polarization is likely to depend critically on the spatial structure of each polymer. In particular, linear polymers make loops, and there is at present no clean theory of the relative importance of polarization transport along the polymer and through monomers well separated in the linear polymer but accidentally close in space. It is even not known whether this transport can be described by a diffusion equation, nor if the average square distance over which polarization is transported is proportional to time. The second reason why the Blumberg approach fails is that it would yield unphysical predictions even if we could use an average polymer structure and a diffusion equation. We see this briefly. Let us assume that in a polymer both equations (33) and (34) are valid. With a density $\rho \propto r^{D-3}$, we obtain for $b \ll R$, and after a little algebra

$$\frac{1}{T_1} \approx \frac{C}{R^D b^{6-D}} \text{ and } \frac{\tau}{T_1} \approx \left(\frac{b}{R}\right)^{D-2} \quad (38)$$

For $D < 2$, the last ratio is larger than unity! This is in contradiction with the hypotheses of the model. The conclusion is that for a system of low dimensionality, diffusion can take over direct relaxation only at distance substantially larger than b as given by equation (33). This conclusion is confirmed by the experimental results on dilute and semi-dilute solutions of polystyrene. As an example, for an angle $\theta = 25^\circ$ between effective and external fields in a dilute solution of polystyrene, the exponential part of the signal corresponds approximately to 30 per cent of the total signal. The distance r_1 beyond which the polarization is homogenized by diffusion corresponds to $(r_1/R)^D \simeq 0.7$ that is $(r_1/R \simeq 0.8)$. We use this value in equation (34), with the integrations between r_1 and R for calculating T_1 . As for the diffusion time, it has to be taken from r_1 to R : $\tau \approx (R - r_1)^2/D$. We obtain finally, with the help of equation (33)

$$\frac{\tau}{T_1} \approx 0.03 \left(\frac{b}{R}\right)^4 \ll 1, \quad (39)$$

which lifts the inconsistency.

It would be pointless to extend the discussion further, both because of the doubtful validity of a spin diffusion equation for a collection of polymers and because it is at distances close to R that the model for the variation of the nuclear density with distance should cease to be strictly valid.

7 CONCLUSION AND PERSPECTIVES

The study of direct spin-lattice relaxation of polymers by fixed paramagnetic centers grafted on the polymers turns out to be indeed a useful complement to their investigation by small angle neutron scattering, in particular for confirming their fractal structure. At the present experimental stage, it cannot be claimed that NMR by itself can actually determine the fractal dimension with great accuracy, but it confirms the findings of SANS from a very different type of approach.

However, NMR has potential capabilities that might go beyond those of SANS. An example provided by the experiments on dilute solutions of polystyrene is the shape of the relaxation decay, distinctly different in its last part from theoretical expectation, which hints at the possibility of refining the form of nuclear density near the edge of the polymer. We list a number of openings for which NMR could equally well provide information essentially unavailable by other means:

- placing the paramagnetic centers in the solvent rather than on the polymers, which could provide information on the space excluded by the presence of the polymers and its shape.
- use of a polycrystalline host in order to reveal whether this has an influence on the polymer shape. This possibility is forbidden to SANS, since the grain boundaries would cause a neutron scattering far larger than that due to the polymers.
- use of partly deuterated polymers, so as to have access to the position of given parts of the polymer relative to the end where the relaxing center is grafted.
- consider other polymer configurations. A general but still preliminary study has in fact been made on the relaxation characteristics of polymers close to a surface where paramagnetic centers are located, either grafted to the surface

or adsorbed by the surface, as a function of the surface density of the polymers with respect to their length.¹⁶ This study also envisioned the interest of using partly deuterated polymers.

1 INTRODUCTION

The first use of nuclear magnetic resonance (NMR) to study glass structure using nuclei having electric quadrupole moments was reported by Silver and Bray in 1958.¹ In that work, the interaction between the nuclear electrical quadrupole moment (possessed by all nuclei having a spin $I > \frac{1}{2}$) and the electric field gradient at the nuclear site is small in comparison with the Zeeman interaction of the nuclear magnetic dipole moment with an externally applied magnetic field. The energy levels and transition frequencies can be calculated² using the quadrupolar interaction as a perturbation of the Zeeman interaction.

It is this case that is discussed and illustrated with specific examples in the following section. Extensive studies of this type have been summarized and referenced in a number of reviews of NMR studies of glasses.^{3–7} (Note that the review by Eckert³ contains, on p. 163, a table of 39 earlier reviews, listing their main topics.) Succeeding sections of this article contain discussions of the cases in which the magnetic field is absent [i.e., pure nuclear quadrupole resonance (NQR) studies], and cases in which the Zeeman interaction is present but sufficiently small to be treated as a perturbation of the quadrupolar interaction.

There will necessarily be some overlap between the material presented in this article and in other portions of the Encyclopedia. Cross references to pertinent subjects are given at the end of the article.

2 NMR WITH A QUADROPOLAR PERTURBATION

Figure 1 displays the energy levels for the case of the pure Zeeman interaction (i.e. no quadrupolar interaction present), and the shifting of those levels when a relatively small quadrupolar interaction is present. The shifts depend on the coupling of the nuclear electrical quadrupole moment eQ with the components of the electric field gradient (EFG) tensor at the nuclear site. These are V_{xx} , V_{yy} , and V_{zz} in the system of principal axes for the EFG. Here V is the electrical potential at the nuclear site arising from charges outside the nucleus, and $V_{xx} = \partial^2 V / \partial x^2$, etc. The shifts also depend on the angles θ

Figure 1 Energy levels arising from the interaction of the nuclear magnetic dipole moment with a magnetic field: (a) no electrical quadrupolar interaction; (b) small quadrupolar interaction present (the levels shown are appropriate for the ^{11}B nucleus)

and ϕ that specify the orientation of the magnetic field $\mathbf{B}$ with respect to the principal axes of the EFG. Since all angles θ and ϕ are equally probable in a finely divided polycrystalline powder or a glass, the NMR spectra for those cases will be the envelope of responses observed for a single crystal as it is placed in all possible orientations in the magnetic field. The resulting theoretical ‘powder pattern’ for a quadrupolar interaction that is sufficiently small to be treated with first-order perturbation theory is displayed in Figure 2 for the case of a nuclear spin $I = \frac{3}{2}$. (No dipolar or other broadening mechanisms have been taken into account.) Here $\chi = e^2 q Q = e^2 V_{zz} Q$ is the quadrupole coupling constant that measures the strength of the quadrupolar interaction, and $\eta = (V_{xx} - V_{yy})/V_{zz}$ is the asymmetry parameter that measures the departure of the EFG from axial symmetry. (With $|V_{zz}| \geq |V_{yy}| \geq |V_{xx}|$, one finds that $0 \leq \eta \leq 1$.) Note that the ‘central’ transition ($m = +\frac{1}{2} \leftrightarrow -\frac{1}{2}$) is unaffected at first-order, and remains at the Larmor frequency ν_0 , while the ‘satellite’ transitions ($m = +\frac{3}{2} \leftrightarrow +\frac{1}{2}$ and $m = -\frac{3}{2} \leftrightarrow -\frac{1}{2}$) are spread out into the ‘powder patterns’.

Broadening mechanisms (e.g., dipolar interactions, and distributions in the EFG components) smooth the divergences in the theoretical powder pattern, and give breadth to the central transition peak. This is exemplified in Figure 3 for the particular case of $\eta = 0$. When use is made of older

Figure 2 First-order quadrupolar spectrum for $I = \frac{3}{2}$ nuclei in a powder or glass. Here $\nu_Q = 3\chi/2I(2I - 1)$

Figure 3 Resonance lineshape (solid curve) predicted for a nucleus such as ^{11}B with a small quadrupolar interaction in a glass or polycrystalline powder. This is the $\eta = 0$ case

CW NMR spectrometers, the recorded resonance is usually the first derivative of the absorption curve. This is displayed in Figure 4 for the ^{11}B ($I = \frac{3}{2}$) response in polycrystalline boron phosphate (BPO_4), for which the value of $\chi = 50.4$ kHz if η is assumed to be zero.⁸ (The boron atom is at the center of a BO_4 tetrahedron that is only slightly distorted, so the components of the EFG are quite small. The EFG vanishes for perfect tetrahedral and octahedral symmetry.)

Figure 5 displays⁹ the derivative response for ^7Li ($I = \frac{3}{2}$) in a glass containing 25 mol% Li_2O and 75 mol% B_2O_3 . If $\eta = 0$ then $\chi \approx 185$ kHz. (The electrical quadrupole moment Q for ^7Li is relatively small.) The partial ‘smearing’ of the divergences in the powder pattern arises from the distribution in the EFG components caused by the disorder of the vitreous state. See Krämer et al.¹⁰ for other examples of ^7Li NMR spectra for glasses.

When the quadrupolar interaction is larger (but still treatable as a perturbation of the Zeeman interaction), the central ($m = \frac{1}{2} \leftrightarrow -\frac{1}{2}$) transition is affected at second order. Figure 6 displays the theoretical pattern for this case, both for $\eta < \frac{1}{3}$ and $\eta > \frac{1}{3}$. The particular case of small or zero η is illustrated in Figure 7

Figure 4 ^{11}B NMR spectrum in boron phosphate (BPO_4); $\nu_0 = 7.177$ MHz

Figure 5 ^7Li NMR spectrum of glass of composition $\text{Li}_2\text{O} \cdot 3\text{B}_2\text{O}_3$

where the dashed lines indicate the theoretical pattern without broadening and the solid line indicates the expected lineshape when broadening is included.

This transition^{11a} for ^{11}B in vitreous boron oxide (B_2O_3) is displayed in Figure 8. In this case, in which all of the boron atoms are at the center of planar triangles of oxygens (i.e., BO_3 units) and all of the oxygens are bridging (i.e., bonded to two borons), one finds $\chi = 2.76$ MHz and $\eta = 0.10$. The departure from perfect trigonal symmetry about the axis perpendicular to the BO_3 units and passing through the boron is small or moderate. One finds for such BO_3 units

Figure 6 Powder patterns for the central transition ($m = -\frac{1}{2} \leftrightarrow m = +\frac{1}{2}$) of half-integer spin nuclei in the presence of second-order quadrupolar interactions for two regimes: $\eta < \frac{1}{3}$ and $\eta > \frac{1}{3}$. Here $\nu_Q = 3\chi/2I(2I - 1)$ and ν_0 is the Larmor frequency

Figure 7 Resonance lineshape (solid curve) for a nucleus with a large quadrupole interaction in a glass or polycrystalline powder. This is the $\eta = 0$ case

that $2.4 \text{ MHz} \leq \chi \leq 2.9 \text{ MHz}$ and $0 \leq \eta \leq 0.2$. (In the case of vitreous B_2O_3 , the BO_3 units are portions of the boroxol structural groupings depicted in Figure 9, but they occur also in other borate structural groupings shown there.)

In alkali borate compounds of 50 mol% or more of alkali oxide, one finds BO_3 units that have one or more nonbridging oxygens (NBO) (i.e., the oxygen is bonded to only one boron and is negatively charged). If the BO_3 unit has one or two of these, the trigonal symmetry noted above is lost, and the asymmetry parameter has been found from NMR spectra to rise into the range $0.4 \leq \eta \leq 0.9$. An example is calcium metaborate ($\text{CaO} \cdot \text{B}_2\text{O}_3$), whose chain structure is depicted in Figure 9. The NMR spectrum^{11a} of this material is displayed in Figure 10. These asymmetric BO_3 units, and the BO_4 and symmetric BO_3 units, are all present in many borate glasses. Responses from all three units are present in the ^{11}B NMR spectrum^{11a} displayed in Figure 11, where the narrow structureless line from BO_4 units is off scale and the symmetric BO_3 units give rise to the middle positive peak on the left and part of one of the negative peaks on the right. The fraction of each type of unit present in the glass can be obtained from the intensity of the corresponding NMR responses, as illustrated in Figure 12 for a low-alkali glass where N_4 is the fraction of four-coordinated borons (i.e. in BO_4 tetrahedra). Figure 13 displays N_4 as a function of the molar fraction x of alkali

Figure 8 ^{11}B NMR spectrum of vitreous B_2O_3 at 16 MHz ^{11b}

Figure 9 Structural groupings found in alkali borate compounds and glasses

oxide in alkali borate glasses.¹² With the composition $x\text{Na}_2\text{O}(1-x)\text{B}_2\text{O}_3$, N_4 is $x/(1-x)$ if each oxygen added as Na_2O converts two borons from three- to four-coordination.

Kirkpatrick and Oldfield and co-workers¹³ have demonstrated that the ^{11}B NMR responses from BO_3 and BO_4 configurations can be separated using magic angle sample spinning (MAS) with high spinning speeds at high magnetic fields. Figure 14 displays the BO_3 and BO_4 responses for polycrystalline $\text{Li}_2\text{O} \cdot 2\text{B}_2\text{O}_3$ and Pyrex glass. (For the Pyrex glass, they conclude that two BO_3 and two BO_4 sites are present. χ for the BO_3 units can be determined to perhaps two significant figures if η is assumed to be zero.)

Quadrupolar effects, then, clearly identify the various boron-oxygen bonding configurations in glasses. That information makes possible the development and validation of structural models for binary,¹⁴ ternary,¹⁵ and more complex glasses containing boron oxide.

Figure 10 (a) Theoretical powder pattern for the transition ($m = +\frac{1}{2} \leftrightarrow m = -\frac{1}{2}$), with $I = \frac{3}{2}$, $\nu_0 = 16 \text{ MHz}$, $\chi = 2.56 \text{ MHz}$, and $\eta = 0.54$. (b) First derivative of the theoretical powder pattern after convolution with a Gaussian curve of linewidth $2\sigma = 5 \text{ kHz}$. (c) Superposition of four experimental traces for ^{11}B in polycrystalline calcium metaborate, at a resonant frequency of 16 MHz ^{11b}

Figure 11 ^{11}B NMR spectrum of (a) a BO_4 unit, (b) a BO_3 unit, (c) a BO_3^- unit (with one NBO), and (d) a sample containing all three units^{11b}

Müller-Warmuth and colleagues¹⁶ have improved the resolution and accuracy, and obtained values of χ for the BO_4 units, using very high speed (e.g. 15 kHz) spinning rates and satellite transition spectroscopy (SATRAS). Very short excitation pulses (e.g., $0.5\ \mu\text{s}$) are used to excite large spectral ranges. Figure 15 displays ^{11}B spectra for a glass of composition (mol%) $33\text{Li}_2\text{O}-67\text{B}_2\text{O}_3$. Values of χ can be determined from the extent of the spinning sidebands or locations of the centers of gravity of the central and satellite transitions, and (for BO_3) computer simulation of the central transition line-shape as narrowed by the MAS procedure.¹⁷ For the glass of Figure 15, the values of quadrupolar parameters found are 2.6 MHz and 0.3 for BO_3 , and 0.80 MHz for BO_4 . (The isotropic chemical shifts for BO_3 and BO_4 can also be determined.)

^{27}Al NMR has been extensively employed to study glass structure. Static NMR investigations have generally revealed only structureless, but asymmetric, lines. But utilization of MAS MMR spectroscopy by D. Müller,¹⁸ Samoson and Lippmaa,¹⁹ Kirkpatrick,²⁰ and Dupree²¹ and their colleagues has yielded separation of Al responses from different sites in glasses due to different chemical shifts (and quadrupolar parameters). Kirkpatrick and co-workers²⁰ clearly identified four-, five-, and six-coordinated aluminum sites in $\text{SiO}_2-\text{Al}_2\text{O}_3$ glasses. Those studies have generally been focused on the chemical shifts, but Müller-Warmuth

The frequency of rotation is 15 kHz (see van Wüllen and Müller-Warmuth¹⁶)

and associates²² have used the high-field, high-spinning-rate SATRAS procedure to obtain both the isotropic chemical shifts and the values of χ for a number of ternary glasses. The value of η was not determined, and χ values are therefore limited to an accuracy of about 14%.

Oxygen bonding in vitreous SiO_2 ²³ and B_2O_3 ²⁴ has been studied using samples substantially enriched in the ^{17}O ($I = \frac{5}{2}$) isotope from the natural abundance of 0.037%. The ^{17}O spectrum in SiO_2 was simulated by only one oxygen site using the parameters $\chi = 5.17$ MHz and $\eta = 0.2$. Changing the value of η or the width of the distributions in χ and η by as much as 30% still yielded an acceptable fit to the experimental spectrum, but the central value (5.17 MHz) of χ could be changed by only 1%. These results can be related to a distribution in the Si–O–Si bond angle between 130° and 180° , which is consistent with an earlier X-ray investigation of SiO_2 glass.

The ^{17}O NMR spectrum for vitreous B_2O_3 , shown in Figure 16, required a two-site fit. Quadrupolar parameters for the two sites are $\chi = 4.69$ MHz, $\eta = 0.58$ and 5.75 MHz, 0.40 . The first site has only small distributions in χ and η , and is assigned to an oxygen in the boroxol ring (see Figure 9). The second site also has a small distribution of χ but a broad distribution in η , and arises from the oxygens connecting boroxol rings. About 83% of the borons in the glass are in boroxol rings. Kirkpatrick and co-workers²⁵ have extended ^{17}O NMR studies to high fields, and have succeeded in assigning features of the quadrupolar induced structure

Figure 16 Two superimposed ^{17}O spectra from B_2O_3 glass and a computer simulation using the quadrupolar parameters given in the text

to oxygens in various bonding arrangements (e.g., Si–O–Si, Na–O–Si, and B–O–B).

Segel and Creel²⁶ prepared vitreous potassium metavanadate and found that the ^{51}V NMR response is the typical ($m = +\frac{1}{2} \leftrightarrow -\frac{1}{2}$) transition displaying second-order quadrupolar effects. The quadrupolar parameters at 300 K are approximately 3.35 MHz and 0.47. These values are in line with those for the crystalline metavanadates,^{26,27} in which each vanadium is enclosed in a tetrahedron of oxygens. In vanadium phosphate glasses²⁸ and crystalline V_2O_5 ,²⁹ in which the vanadiums are five-coordinated to oxygens in VO_5 units, the values of χ are found by NMR to be lower. The value²⁹ in crystalline V_2O_5 is 805 kHz (with $\eta = 0.04$), and rough estimates of χ for the vanadium phosphate glasses are in the 1.0–1.5 MHz range.²⁸

The reader is directed to the review by Eckert³ for summaries of, and references for, similar works on boron-doped amorphous silicon, boron in metal–metalloid glasses, gallium and arsenic studies of GaAs and GaP amorphous semiconductors, deuteron studies of ‘water’ in glasses, glasses based on B_2S_3 , B_2Se_3 , Ga_2O_3 , and BeF_2 , glasses containing Na_2O and Cs_2O , and other quadrupolar nuclei in glasses.

3 PURE NUCLEAR QUADRUPOLE RESONANCE (NQR) STUDIES

Since the quadrupolar interaction generates a set of energy levels in the absence of a magnetic field, transitions between these levels will yield resonance spectra if the spectrometers employed are sufficiently sensitive in the relevant frequency regions. These zero field NMR studies are labeled pure nuclear quadrupole resonance (NQR) spectroscopy.

Pure NQR spectra in solids were first detected by Dehmelt and Kruger in 1950.³⁰ A large body of NQR studies of chemical bonding and atomic arrangements in crystalline solids, using quadrupolar nuclei, has followed from that discovery and continues to expand (see, e.g., the summaries by Lucken,³¹ Schempp and Bray,³² Semin et al.,³³ and Rubenstein and Taylor^{34,35}). The following sections summarize the application of NQR to glass studies employing particular nuclei.

3.1 ^{75}As NQR

The first detection of NQR in a glass was reported by Rubenstein and Taylor in 1972³⁴ and extended by Taylor and colleagues.^{35,36} Rubenstein and Taylor³⁴ employed the spin $I = \frac{3}{2}$ nucleus ^{75}As in vitreous arsenic trisulfide (As_2S_3). The extended studies^{35,36} also encompassed vitreous arsenic telluride and elemental arsenic.

The Hamiltonian for the pure quadrupolar interaction is³⁷

$$\hat{\mathcal{H}} = \frac{\chi}{4I(2I-1)} [3\hat{I}_z^2 - I(I+1) + \frac{1}{2}\eta(\hat{I}_+^2 + \hat{I}_-^2)] \quad (1)$$

where $\hat{I}_\pm = \hat{I}_x \pm i\hat{I}_y$. When $I = \frac{3}{2}$, the secular equation (with E in units of $\frac{1}{4}\chi$) is

$$E^2 - (1 + \frac{1}{3}\eta^2) = 0 \quad (2)$$

and the frequency ν_0 of the single allowed transition between the $m = \pm\frac{3}{2}$ and $m = \pm\frac{1}{2}$ states, both of which are degenerate in the absence of a magnetic field, is

$$\nu_0 = \frac{1}{2}\chi\sqrt{1 + \frac{1}{3}\eta^2} \quad (3)$$

(Clearly, the values of χ and η cannot be independently extracted from this one transition. Methods to determine η , and thus χ , independently are discussed later in this article.)

The transition at frequency ν_0 given in equation (3) was observed by Rubenstein and Taylor³⁴ for crystalline (orpiment) and vitreous As_2S_3 at 4.2 K using a variable frequency pulsed NQR/NMR spectrometer and observing the frequency dependence of the spin echo amplitude. Figure 17 displays the data points and fitted Gaussian curve for the glass; the two narrower lines in the 70–73 MHz region are data for crystalline As_2S_3 . The latter resonances occur at 70.38 and 72.86 MHz with respective halfwidths at half-maximum amplitude (HWHM) of 87 and 44 kHz. (There are two inequivalent As sites in the known structure of orpiment.)

Figure 17 ^{75}As NQR in glassy and crystalline As_2S_3 at 4.2 K. The solid circles are experimental points for the glass through which a Gaussian curve has been drawn. The two narrow lines are data for crystalline As_2S_3 (see Rubenstein and Taylor³⁴)

But the glass yields only one very broad response centered at 71.6 MHz and having an HWHM of 3.5 MHz.

Orpiment has a layer structure in which each As atom is bonded to three S atoms in a triangular pyramidal arrangement with an As atom at the apex and three S atoms at the base. Rubenstein and Taylor³⁴ assumed that the large breadth of the lineshape in the As_2S_3 glasses arises from a distribution of distortions in the apex angles α . Since a difference of 1.3° between the α values for the two sites in orpiment produces a difference of 3.48 MHz between the NQR responses, a distribution of apex bonding angles α with a halfwidth of 2° will produce a distribution of frequencies with the observed halfwidth of 3.5 MHz for the glass. (The analysis assumes that the sites present in orpiment, and yielding the observed NQR frequencies, are present in the As_2S_3 glass. This has been placed in question by the work of Szeftel and Alloul that is discussed later in this article.)

In a later study, Rubenstein and Taylor³⁵ detected and analyzed the pure NQR spectra for crystalline and vitreous As_2Se_3 and obtained a better-resolved spectrum for vitreous As_2S_3 . They also measured the spin–lattice relaxation time T_1 at various temperatures. From the near equality of the As_2S_3 crystalline and amorphous initial relaxation behavior, they concluded that the near-neighbor environments of As atoms in the crystal and the glass are quite similar (i.e., the two sites in orpiment, and two-dimensional correlations between As_2S_3 pyramidal units in the layer-structured crystalline phase, are retained in the glass).

Application of a small magnetic field at a series of orientations of an orpiment single crystal yielded data that, based on calculations by Bersohn³⁷ and Dean,³⁸ yielded values of the asymmetry parameter for the two sites in the crystal that Rubenstein and Taylor concluded are also present in the glass. This case of a Zeeman perturbation of an NQR spectrum is discussed in the next section. The values of η for the two sites are 0.343 and 0.374.

Jellison, Petersen, and Taylor³⁶ reported in 1980 an NQR study of amorphous, orthorhombic, and rhombohedral arsenic. Figure 18 displays the highly asymmetric response for the arsenic glass, and the much narrower line for orthorhombic arsenic. Jellison et al. found that the asymmetric pattern obtained for the glass could be reproduced in a calculation by varying the dihedral angle using distributions in the angle

Figure 18 NQR absorption in amorphous As (circles and solid line) and orthorhombic As (dashed line) at 4.2 K (see Jellison et al.³⁶)

suggested in the literature. (The dihedral angle is the angle of rotation along the As–As bond required to bring the pair into an eclipsed position.) The temperature dependence of the NQR frequencies for the crystalline forms of arsenic were obtained, and could be well fitted by the customary Bayer model,³⁹ but the NQR lineshape for the arsenic glass is too broad for observation of shifts in the peak frequency with temperature.

In more recent studies,⁴⁰ Taylor and colleagues have used ^{75}As NQR and ^{63}Cu NMR spectroscopy to study chalcogenide glasses in the systems Cu–As–S and Cu–As–Se.

3.2 ^{11}B and ^{10}B NQR

The NQR resonance frequencies, predicted from the quadrupolar effects observed in NMR studies, for many other quadrupolar nuclei in glasses (e.g., ^7Li , ^{10}B , ^{11}B , ^{14}N , ^{17}O , ^{23}Na , ^{27}Al , ^{39}K , and ^{51}V) lie below 10 MHz and even below 1 MHz. Sufficient signal-to-noise (S/N) values for detection of those responses can be very difficult to achieve. However, a modified Robinson circuit,⁴¹ placing the entire inductive-capacitive tank circuit at 77 K and utilizing state-of-the-art solid state components and Zeeman modulation, has achieved high S/N at low frequencies. Figure 19 from Gravina and Bray,⁴² displays the ^{11}B NQR spectrum for crystalline boron oxide (B_2O_3). (^{11}B has spin $I = \frac{3}{2}$, and equation (3) predicts the NQR frequency.) A S/N value between 100 and 200 is easily obtained at this frequency of 1.358 MHz. Figure 20 displays a vertically expanded version of Figure 19 in which the highest frequency of 13 allowed ^{10}B transitions is seen in full detail. (^{10}B is 18.8% and ^{11}B 81.2% abundant in nature.)

In light of the extreme width of the ^{75}As NQR spectra in amorphous As and vitreous As_2S_3 and As_2Se_3 , one might anticipate failure in seeking the ^{11}B NQR spectrum in borate glasses near 1.35 MHz. But, if those widths of some megahertz are caused by distributions in the EFG components, they will scale with the resonance frequency. Figure 21 displays the ^{11}B NQR spectrum for vitreous B_2O_3 . The full width at half-maximum (FWHM) is 21 kHz. This is only a moderate increase in width from the FWHM of 15 kHz, arising from

Figure 19 Boron NQR spectrum of crystalline B_2O_3

Figure 20 The features of Figure 19 displayed with a greatly expanded vertical scale

Figure 21 ^{11}B responses from vitreous B_2O_3

dipolar broadening, in crystalline B_2O_3 . The larger response in Figure 21 must arise from borons in the boroxol groups that predominate²⁴ in the glass (see Figure 9). The site for the borons yielding the lower-frequency response in Figure 21 has not yet been identified.

Some work has been completed in ^{11}B NQR studies of structural arrangements and chemical bondings in alkali borate glasses. According to the model proposed by Krogh-Moe⁴³ and supported (but not proved) by the ^{11}B and ^{10}B NMR studies of Bray and co-workers,⁴⁴ those glasses should be composed of mixtures of the structural groupings presented in Figure 9. As an indication of the sensitivity of the ^{11}B NQR resonance frequency to the particular structural grouping in which the BO_3 or BO_4 units are located, it is instructive to study Figure 22. The sample under study was prepared as polycrystalline sodium tetraborate ($\text{Na}_2\text{O} \cdot 4\text{B}_2\text{O}_3$), but X-ray diffraction showed the material to be a mixture of sodium borate compounds. ^{11}B NQR responses from at least six sites are resolved in the spectrum displayed in Figure 22, and they span a range of some 150 kHz. There is hope, then, of identifying the particular structural groupings present in any

Figure 22 ^{11}B responses from a polycrystalline sample having the sodium tetraborate composition ($\text{Na}_2\text{O} \cdot 4\text{B}_2\text{O}_3$)

borate glass, and even gaining a measure of the amount of each grouping present.

An example of the degree of correspondence between the ^{11}B NQR spectra for crystal and glass is displayed in Figure 23. The spectrum in (a) is for polycrystalline sodium diborate ($\text{Na}_2\text{O} \cdot 2\text{B}_2\text{O}_3$), and the spectrum for the glass is in (b). The crystal is known from X-ray diffraction studies to consist of sodium ions and diborate groupings (see Figure 9). Figure 24 shows the ^{11}B NQR spectrum for a glass of molar composition $0.15 \text{Na}_2\text{O} - 0.85\text{B}_2\text{O}_3$, with the spectrum for vitreous B_2O_3 superposed. It is clear that there are at least three different structural groupings present in the sodium borate glass, and that one of them is probably the boroxol unit found in vitreous B_2O_3 . On the basis that the structural groupings from the crystalline compounds nearest in composition to the glass should predominate, the other responses may arise from the tetraborate group or the pentaborate and triborate groups that can join to form the tetraborate structural grouping (see Figure 9).

3.3 ^{27}Al NQR

The Robinson-type CW spectrometer has been used successfully⁴⁵ to detect ^{27}Al NQR spectra in polycrystalline powders and glasses at relatively low frequencies. ^{27}Al has spin $I = \frac{5}{2}$, and the secular equation for the energy values E (with E in units of $\frac{1}{20}\chi$) is

$$E^3 - 7(3 + \eta^2)E - 20(1 - \eta^2) = 0 \quad (4)$$

Numerical solution via a computer program yields the values of E and the transition frequencies for any set of values of χ and η .

Figure 25 displays the two NQR responses for ^{27}Al in a glass of composition (mol%) of $16.8\text{Al}_2\text{O}_3 - 83.2\text{TeO}_2$ at 77 K. The frequencies are 490.1 and 853.3 kHz and the widths (FWHM) are approximately 15 kHz. Values of $\chi = 2.909 \pm 0.014 \text{ MHz}$ and $\eta = 0.346 \pm 0.014$ were obtained from the

Figure 23 ^{11}B NQR spectra of (a) crystalline and (b) vitreous $\text{Na}_2\text{O} \cdot 2\text{B}_2\text{O}_3$

data. An NMR measurement yielded an isotropic chemical shift of 36.7 ppm, which identifies a pentahedrally coordinated aluminum site.

It is clear that NQR studies of aluminum in four-, five-, and six-coordination in glasses are feasible and very accurate in measurements of the quadrupolar parameters.

4 NQR WITH A ZEEMAN PERTURBATION

We now survey the case in which a small magnetic field is present during the NQR experiment. This Zeeman splitting of a pure NQR spectrum was first treated by Bersohn³⁷ using a perturbation procedure. Dean³⁸ subsequently treated the theory of Zeeman splitting rigorously, and discussed the case of nuclear spin $I = \frac{3}{2}$ in detail. The applied field lifts the degeneracy of the $m = \pm\frac{3}{2}$ and $m = \pm\frac{1}{2}$ states, yielding the energies⁴⁶ and transition frequencies displayed in Figure 26.

Rubenstein and Taylor³⁵ applied the expressions for the four transition frequencies $\omega_i = \nu_i$, $i = 1, \dots, 4$ to rotations about the a , b , and c axes of a single crystal (orpiment) of As_2S_3 , using a magnetic field of about 87.5 mT. (The Zeeman interaction in this field would be 638 kHz, whereas the NQR frequencies are in the 70–72 MHz range. A first-order perturbation treatment of the Zeeman interaction is adequate.)

Figure 24 ^{11}B NQR spectrum of a glass of composition $0.15\text{Na}_2\text{O}-0.85\text{B}_2\text{O}_3$ referenced to vitreous B_2O_3

Figure 25 The two ^{27}Al NQR responses for vitreous $16.8\text{Al}_2\text{O}_3-83.2\text{TeO}_2$ (mol%)

The values of η extracted for the two inequivalent As sites in orpiment are 0.343 and 0.374.

Szeftel and Alloul⁴⁷ employed the frequency Ω_1 in Figure 26 to determine the value of the asymmetry parameter for ^{75}As in several vitreous chalcogenides. (In theory, Ω_3 could also be used, but the transition probability is lower than for Ω_1 . No response was detected⁴⁷ at Ω_3 .) The frequency Ω_1 is given by

$$\Omega_1 = \Omega \left[\left(1 - \frac{2}{\rho} \right)^2 \cos^2 \theta + \left[\left(1 + \frac{1}{\rho} \right)^2 + \frac{\eta^2}{\rho^2} - 2 \frac{\eta}{\rho} \left(1 + \frac{1}{\rho} \right) \cos 2\phi \right] \sin^2 \theta \right]^{1/2} \quad (5)$$

where $\Omega = \gamma B$, γ is the gyromagnetic ratio, and $\rho = 1 + \frac{1}{3}\eta^2$. Since equation (4) does not include the quadrupolar coupling constant χ , this transition can be used to obtain the value of η quite decoupled from that of χ .

Figure 26 Energy level diagram for a nuclear spin $I = \frac{3}{2}$ in the presence of a strong quadrupolar coupling and, respectively, zero and nonzero Zeeman perturbation (see Szeftel and Alloul⁴⁷)

Prediction of the observable lineshape for a polycrystalline powder or glass requires averaging over all θ and ϕ , including the dependence of the state functions and transition probabilities on those angles. Figure 27 displays the calculated lineshapes for two values of η . The parameter $r = \Omega/\nu = \gamma H_0/\nu$, where ν is the frequency of the spectrometer, has the limits $r_m \leq r \leq r_M$, and a logarithmic divergence occurs at r_p , where

$$\left. \begin{aligned} r_m &= \left[1 + \frac{1+\eta}{\rho} \right]^{-1}, & r_M &= \left(\frac{2}{\rho} - 1 \right)^{-1} \\ r_p &= \left[1 + \frac{1-\eta}{\rho} \right]^{-1} \end{aligned} \right\} \quad (6)$$

The ^{75}As spectra obtained at 4.2 K for four vitreous chalcogenides are displayed in Figure 28. Analysis of the spectra was carried out using Gaussian distributions in η about the value determined at the logarithmic divergence (τ_p). For vitreous As_2S_3 and As_2Se_3 , it was found necessary to include the contributions from two As sites with distinctly different values of η . These were determined as 0.12 and 0.36 for vitreous As_2S_3 , whereas the values for crystalline orpiment found by Rubenstein and Taylor³⁵ using a single crystal are 0.343 and 0.374. The site with $\eta = 0.12$ is clearly not present in orpiment, and is a site not considered by Rubenstein and Taylor³⁵ in their discussions of the ^{75}As NQR spectrum for vitreous As_2S_3 . For vitreous As_2Se_3 , the values of η were determined by Szeftel and Alloul⁴⁷ to be 0.14 ± 0.02 and 0.45.

Figure 27 Spectra (solid lines) calculated for two values of η (see Szeftel and Alloul⁴⁷)

Figure 28 ^{75}As spectra recorded in four vitreous chalcogenides at 5.9 MHz (circles) and 10.3 MHz (crosses). The powder spectrum calculated with the η values of orpiment is plotted as dash-dotted lines. Solid lines indicate the best fit. When two Gaussian distributions are needed to obtain the best fit, the contribution of the distribution of higher weight is plotted as a dashed line (see Szeftel and Alloul⁴⁷)

1 INTRODUCTION

Amphiphilic molecules (surfactants) consist of a polar, often charged, headgroup linked to one or two hydrocarbon, usually alkyl, chains. In the presence of water and possibly additional components, such as long-chain alcohols, alkanes, or simple electrolytes, surfactants spontaneously assemble into finite aggregates (micelles) or build up structures that extend indefinitely in one, two, or three dimensions. This gives rise to numerous liquid crystalline phases, differing in their macroscopic translational and rotational symmetries and displaying a fascinating geometrical and topological variety in their self-assembled microstructure.^{1–6} The structural and dynamic characterization of these phases and the rationalization of their microstructure and phase behavior in terms of intermolecular and interaggregate forces is a challenging task. The importance of amphiphilic liquid crystals derives partly from their biological significance and diverse technical applications. In a more general context, amphiphilic liquid crystals are prime examples of complex fluids (soft matter) and their study has proven to be a rich source of fundamental knowledge.

Nuclear magnetic resonance has contributed more than any other technique to the understanding of amphiphilic liquid crystals. The NMR experiments used in this field are basically of three kinds: lineshape, diffusion, and relaxation studies. Spectral lineshapes from powder samples are now used routinely to distinguish among cubic, uniaxial, and biaxial phases (see *Lytotropic Liquid Crystalline Samples*). Pulsed field gradient spin echo experiments can, under favorable conditions, provide the principal components of the macroscopic diffusion tensor for various molecular components (see *Liquid Crystalline Samples: Diffusion*). Nuclear spin relaxation can provide detailed information about structure and dynamics on a wide range of length and time scales. As compared with lineshapes and diffusion, spin relaxation is a less direct source of information and therefore requires a more elaborate theoretical framework for its interpretation. On the other hand, liquid crystals can yield a large amount of relaxation data, including a variety of spin relaxation rates associated with high-rank

polarization modes, and their dependence on Larmor frequency and sample orientation.

The first spin relaxation studies of amphiphilic liquid crystals appeared in the late 1960s. In a seminal contribution from the early years, Charvolin and Rigny⁷ identified the three main sources of spin relaxation as: (i) local, orientationally restricted motions (rotational isomerization in the case of surfactant chains); (ii) molecular diffusion over curved interfaces; and (iii) collective director fluctuations. It was not until the 1980s, however, that improved instrumental capabilities, new pulse techniques, and advances in relaxation theory established nuclear spin relaxation as a major source of quantitative information about amphiphilic liquid crystals.^{8,9} This is a highly interdisciplinary field of study where ideas and methods are continuously exchanged with several related fields, most notably molecular (thermotropic) liquid crystals and phospholipid bilayers (see Related Articles in Section 6).

2 RELAXATION MECHANISMS AND EXPERIMENTAL METHODS

2.1 General Considerations

The proton is not an ideal nucleus for relaxation studies of amphiphilic liquid crystals due to the complex relaxation behavior of the strongly coupled aliphatic chain protons, the rapid exchange of labile headgroup protons, and the contribution from intermolecular dipole–dipole couplings. Fortunately, there are several other nuclei more suitable for relaxation studies, e.g. ²H or ¹³C in surfactant chains, and ²H or ¹⁷O in water. For studies of microstructure, the choice is restricted to nuclei that are effectively confined to the interface, i.e. surfactant headgroup nuclei (e.g. ¹⁴N), counterion nuclei (e.g. ²³Na), or ²H nuclei in the α -position of the surfactant chain.

Despite important advances in recent years, the complex spin-dynamical behavior of quadrupolar nuclei and coupled spin- $\frac{1}{2}$ nuclei (such as ¹³C¹H₂) in liquid crystals has not yet been fully explored. Since most of the relevant nuclei have spin $I > \frac{1}{2}$, we emphasize quadrupolar relaxation. With the exception of $I \geq \frac{3}{2}$ nuclei, most pulse techniques for relaxation studies of anisotropic systems have been developed in other fields (see *Deuteron Relaxation Rates in Liquid Crystalline Samples: Experimental Methods*); only a brief discussion is included here.

2.2 Quadrupolar Relaxation

Nuclei with $I \geq 1$ are coupled to the molecular degrees of freedom via the interaction of their electric quadrupole moment with the electric field gradient (EFG) generated by the surrounding charge distribution (see *Quadrupolar Interactions*). The first-order effect of the quadrupole coupling is to split the resonance into $2I$ equidistant lines (see *Quadrupolar Nuclei in Solids*). The quadrupole splitting occurs in all noncubic phases and contains information about the orientational order in the phase. In all but the simplest cases, however, the quadrupole splitting yields a product of order parameters, associated with different orientational

degrees of freedom, which cannot be separated without recourse to additional (e.g. relaxation) data.

The principal second-order effect of the quadrupole coupling is to induce spin relaxation (see *Relaxation Theory for Quadrupolar Nuclei*). All information about liquid crystal structure and dynamics that can be derived from quadrupolar relaxation rates is contained in the three lab-frame spectral densities (LFSDs) $J_{kk}^L(k\omega_0; \Omega)$ with $k = 0, 1, 2$:

$$J_{kk}^L(k\omega_0; \Omega) = \int_0^\infty d\tau \cos(k\omega_0\tau) [\langle V_k^{L*}(0) V_k^L(\tau) \rangle - |\langle V_k^L \rangle|^2] \quad (1)$$

which are functions of the magnitude $B_0 = \omega_0/\gamma$ and orientation Ω (with respect to the liquid crystal) of the external magnetic field. The quantity within brackets in equation (1) is the time autocorrelation function of the k th spherical component V_k^L (in the lab frame) of the EFG tensor. The secular ($k = 0$) spectral density contains information about motions on all timescales (within the motional narrowing regime), while the nonsecular ($k = 1, 2$) spectral densities are affected only by motions on the timescale $1/\omega_0$ or faster. To determine the three individual LFSDs at a given magnetic field, one needs to measure at least three independent relaxation rates.

A system of spin I nuclei admits nonequilibrium states with magnetic tensor polarization of rank $k = 1, 2, \dots, 2I$ and coherence order $q = 0, \pm 1, \dots, \pm k$. The spin system can thus be described in terms of $(2I + 1)^2 - 1$ state multipoles¹⁰ of rank k and projection index q . The axial ($q = 0$) multipole components, referred to as polarizations or alignments, are the generalizations of longitudinal magnetization ($k = 1, q = 0$). The remaining ($q \neq 0$) multipole components, referred to as q quantum coherences, are the generalizations of transverse magnetization ($k = 1, q = \pm 1$). The effect of hard radiofrequency pulses is simply to rotate the state multipoles, i.e. to mix the quantum order q without affecting the tensor rank k , whereas evolution under the (fluctuating) quadrupolar Hamiltonian mixes the rank without affecting the quantum order.¹¹

In noncubic liquid crystals, the evolution of the polarizations involves $2I$ generalized longitudinal relaxation rates which depend on the two nonsecular LFSDs. (This dependence is linear for $I = 1$ and $I = \frac{3}{2}$, but nonlinear for $I \geq \frac{5}{2}$.) The principal longitudinal relaxation experiments are the classical inversion–recovery and Jeener–Broekaert experiments¹² and their generalizations.¹³

The evolution of the coherences involves $I(2I + 1)$ generalized transverse relaxation rates, some of which may be degenerate. The homogeneous linewidths of satellite peaks, i.e. spectral lines that exhibit a first-order quadrupolar shift, are linear combinations of all three LFSDs, whereas the widths of the unshifted central peaks are linear combinations of the two nonsecular LFSDs. (This linear dependence of the linewidths on the LFSDs holds only if the quadrupole splitting is large compared with the nonsecular linewidth.)

Accurate measurements of homogeneous linewidths require echo experiments to refocus dephasing due to spatial inhomogeneities in the magnetic field and in the (static) quadrupole coupling (usually due to imperfect alignment). Whereas either 1D or 2D experiments can be performed on $I = 1$ nuclei,

Table 1 Number of Independent Spin Relaxation Rates for Quadrupolar Nuclei in Non-Cubic Liquid Crystals

Relaxation rate	$I = 1$	$I = \frac{3}{2}$	$I = \frac{5}{2}$	$I = \frac{7}{2}$
Longitudinal	2	3	5	7
Transverse ^a	2	2	6	10
secular	1	1	3	6
nonsecular	1	1	3	4

^aFrom homogeneous linewidths only.

2D experiments are indispensable for $I \geq \frac{3}{2}$ nuclei. The nonsecular central linewidths, associated with the $-q/2 \leftrightarrow q/2$ transitions, are obtained from 2D spin echo experiments, while the secular satellite linewidths are obtained from 2D quadrupolar echo experiments.^{14–16} Table 1 lists the number of distinct relaxation rates that can be measured for different quadrupolar nuclei.

2.3 Dipolar Relaxation

For studies of local surfactant dynamics one can use the ^{13}C nuclei in the alkyl chain, which are relaxed by the dipole–dipole coupling to directly bonded protons. The relaxation behavior of a weakly coupled AX_2 spin system such as $^{13}\text{C}^1\text{H}_2$ is complicated by ^{13}C – ^1H cross relaxation, which is the basis of the nuclear Overhauser effect (NOE), and by cross correlation (interference) between the two C–H pairs which leads to the formation of high-rank polarization (three-spin order).¹⁷ The ^{13}C longitudinal relaxation becomes effectively exponential, however, if the protons are decoupled by strong irradiation and if relaxation within the (strongly coupled) proton spin system quenches the development of high-rank polarization.¹⁸ The ^{13}C inversion–recovery and steady-state NOE are then determined by the three LFSDs $J_{kk}^L(\omega_C + (k - 1)\omega_H; \Omega)$ with $k = 0, 1, 2$, defined as in equation (1) but with V_k^L now denoting the spherical components of the ^{13}C – ^1H dipole–dipole interaction tensor.

2.4 Relaxation Anisotropy and Phase Symmetry

For a system as complex as an amphiphilic liquid crystal, the LFSDs obtained from spin relaxation experiments are usually not amenable to direct physical interpretation without recourse to detailed structural and dynamic models. However, by transforming the lab-frame components V_k^L of the interaction tensor to a crystal-fixed frame, the LFSDs can be decomposed as

$$J_{kk}^L(\omega_k; \Omega) = \sum_{n,p} F_{knp}(\Omega) J_{np}^C(\omega_k) \quad (2)$$

where $\omega_k = k\omega_0$ for quadrupolar relaxation and $\omega_k = \omega_A + (k - 1)\omega_X$ for longitudinal dipolar relaxation of nucleus A coupled to nucleus X. When the time reversal invariance present in all dynamic models of interest has been taken into account there are 15 crystal-frame spectral densities (CFSDs) $J_{np}^C(\omega_k)$, defined in analogy with equation (1). Depending on the rotational symmetry of the liquid crystal, some of these CFSDs

Table 2 Number of Independent Crystal-frame Spectral Density Functions (N) and Second-rank Order Parameters (n_2) for Different Crystallographic Point Groups

Phase	Point group	N	n_2
Isotropic fluid	K_h	1	0
Cubic	O_h	2	0
Lamellar, nematic U, hexagonal	$D_{\infty h}, D_{6h}$	3	1
Tetragonal, rhombohedral	D_{4h}, D_{3d}	4	1
Rectangular, orthorhombic, nematic B	D_{2h}	6	2
Oblique	C_{2h}	9	3
Monoclinic	C_i	15	5

may vanish or be linearly dependent. Taking the rotational symmetry into account, equation (2) can be expressed as¹⁹

$$J_{kk}^L(\omega_k; \Omega) = \sum_{\lambda} F_{k\lambda}(\Omega) J_{\lambda}^C(\omega_k) \quad (3)$$

with the composite index $\lambda = (\alpha, \mu, \mu')$ labeling the irreducible representations α of the liquid crystal point group and the independent subspaces μ of α . The irreducible CFSDs $J_{\lambda}^C(\omega_k)$, constructed from symmetry-adapted tensor components, constitute the complete model-independent information content of a fixed-field spin relaxation study of a liquid crystal.¹⁹ The number N of independent CFSD functions is given in Table 2 for liquid crystals of different symmetry. By measuring three linearly independent spin relaxation rates at N different orientations Ω of the (homeotropically aligned) liquid crystal, one can thus determine the $3N$ quantities $J_{\lambda}^C(\omega_k)$. This relative wealth of model-independent information (as compared to isotropic fluids) imposes severe constraints on models of structure and dynamics.

In isotropic powder samples, the relaxation of the central peak ($-q/2 \leftrightarrow q/2$ transition) for noncubic phases and of the single peak for cubic phases is governed by the isotropically averaged (by interdomain exchange) LFSD:¹⁹

$$J_{\text{iso}}^L(\omega_k) = \frac{1}{5} \sum_{\alpha} d_{\alpha} \sum_{\mu} J_{\alpha\mu\mu}^C(\omega_k) \quad (4)$$

with d_{α} being the dimension of the irreducible representation α .

While the rotational symmetry of a liquid crystal is determined by its crystallographic point group, the observable manifestations of this symmetry depend on the tensor rank of the measured physical property. The powder lineshape, being determined by the (motionally averaged) second-rank EFG tensor, can only distinguish between effectively isotropic, uniaxial, and biaxial symmetries. This is reflected in the number n_2 of independent second-rank order parameters (see Table 2). The CFSDs, involving products of two components V_k^L of a second-rank tensor, can be decomposed into terms transforming as tensors of rank 0, 2, and 4; hence there are $N = 1 + n_2 + n_4$ independent CFSDs.¹⁹ Phases with the same ‘second-rank symmetry’ can thus have different relaxation behavior (see Table 2). On the other hand, since spin relaxation does not involve a higher tensor rank than 4, the relaxation anisotropy is of the same form for hexagonal phases (sixfold symmetry) as for lamellar and uniaxial nematic phases (full cylindrical symmetry). Since the second-rank spherical components V_n transform according to the

Figure 1 Anisotropy of the nonsecular lab-frame spectral densities obtained from the counterion ^{23}Na relaxation in the hexagonal²⁰ and (nonclassical) lamellar²¹ phases of the sodium dodecyl sulfate/decanol/water system at 25 °C. The curves are fits according to equation (5)

irreducible representations (A_1 , E_1 , and E_2) of the point group $D_{\infty h}$, the relaxation anisotropy for these phases takes the form:

$$J_{kk}^L(\omega_k; \beta) = \sum_{n=0}^2 (1 - \delta_{n0}/2) \{ [d_{kn}^2(\beta)]^2 + [d_{k-n}^2(\beta)]^2 \} J_{nn}^C(\omega_k) \quad (5)$$

where the $d_{kn}^2(\beta)$ are reduced Wigner functions and β is the angle between the magnetic field and the symmetry axis of the phase. Figure 1 shows the nonsecular ^{23}Na relaxation anisotropy of counterions in a hexagonal phase²⁰ and in a lamellar phase with disrupted bilayers.²¹ In each case, the fit of equation (5) to the LFSD data yields the six model-independent CFSDs $J_{nn}^C(k\omega_0)$ with $k = 1, 2$ and $n = 0, 1, 2$.

2.5 Relaxation Dispersion and Low-Frequency Dynamics

The dynamic processes responsible for spin relaxation in amphiphilic liquid crystals take place mainly on three time scales: local, restricted motions (1–100 ps), molecular

diffusion over curved interfaces (1–10 ns), and collective processes (> 100 ns). While the local motions are usually in the extreme narrowing limit, the dispersion of the surface diffusion contribution to the nonsecular spectral densities is in the frequency range ($\omega_0/2\pi \approx 1$ –100 MHz) accessible by conventional relaxation experiments. While the secular spectral density $J_{00}^L(0)$ reflects motions on all timescales, special techniques are required to investigate the low-frequency dispersion associated with collective processes.

Two methods are available for probing the secular LFSD $J_{00}^L(\omega)$ in the kHz frequency range. For $I = 1$ nuclei, the quadrupolar echo train $(\pi/2)_x - [\tau - (\pi/2)_y - \tau]_n$ yields an effective spectral density²²

$$\begin{aligned} & \frac{8}{\pi^2} \sum_{n=0}^{\infty} (2n+1)^{-2} J_{00}^L \left((2n+1) \frac{\pi}{2} \omega_p \right) \\ &= J_{00}^L(0) \left[1 - \omega_p \tau_c \tanh \left(\frac{1}{\omega_p \tau_c} \right) \right] \end{aligned} \quad (6)$$

with $\omega_p = 1/\tau$ the pulse train frequency. The second form in equation (6) holds only if $J_{00}^L(\omega)$ is Lorentzian, with correlation time τ_c . Relaxation in the presence of a spin lock field B_1 yields, in a $T_{1\rho}$ experiment on $I = 1$ nuclei, an effective spectral density given approximately by²³

$$\frac{(2\Omega_1)^2}{\omega_Q^2 + (2\Omega_1)^2} J_{00}^L \left(\sqrt{\omega_Q^2 + (2\Omega_1)^2} \right) \quad (7)$$

with $\Omega_1 = \gamma B_1$ and ω_Q the static (residual) quadrupole frequency. If $J_{00}^L(\omega)$ is Lorentzian, equation (7) has a maximum of $J_{00}^L(0)(\sqrt{1+x^2}+x)^{-2}$ at $\Omega_1 = (\omega_Q/2)(1+x^{-2})^{1/4}$, with $x = \omega_Q \tau_c$.

A much wider frequency range, from the conventional MHz range down to ca. 100 Hz, can be explored by the field cycling technique²⁴ (see *Field Cycling Experiments*). Unfortunately, this technique is not applicable to rapidly relaxing quadrupolar nuclei; so far only ^1H field cycling studies of amphiphilic liquid crystals have been reported. As seen from Figure 2, the entire dispersion due to collective processes can be obtained in this way.²⁵

3 ORDER AND DYNAMICS AT THE MOLECULAR LEVEL

3.1 Water and Counterions

Amphiphilic interfaces induce only small and short-ranged perturbations of the strongly hydrogen-bonded network in liquid water. Since the surface-induced orientational order and reorientational anisotropy are weak, the three LFSDs are equal, $J_{kk}^L(\omega_k) = J_{00}^L(0)$, and the spin relaxation exhibits neither anisotropy nor dispersion. Water reorientation in the first molecular ‘layer’ is typically slowed down by a factor of two to three, and there is no evidence for long (> 100 ps) water residence times in any amphiphilic system. Water ^2H and ^{17}O relaxation rates thus report essentially on the fast, local water dynamics, which are insensitive to variations in microstructure.^{26,27}

Figure 2 Dispersion of the longitudinal relaxation rate R_1 of surfactant chain protons in powder samples of the lamellar, hexagonal, and cubic phases of the potassium dodecanoate/ D_2O system at 70°C ²⁵

Counterion relaxation rates reflect fast, local motions as well as slower motions, e.g. diffusion over curved interfaces. The relative contributions from fast and slow motions can be estimated²⁶ as $\langle \chi^2 \rangle \tau_f$ and $\langle \chi^2 \rangle \tau_s$, respectively, where $\langle \chi^2 \rangle$ is the mean square quadrupole coupling constant (QCC), $\langle \chi \rangle$ the residual QCC (averaged by the fast motions), and τ_f and τ_s the effective correlation times. As in the case of water, the residual anisotropy is weak ($\langle \chi \rangle^2 \ll \langle \chi^2 \rangle$), and the fast-motion contribution to the LFSDs is independent of orientation and frequency.²⁰ However, the ratio τ_s/τ_f is typically (in the presence of curved interfaces) an order of magnitude larger for counterions than for water, making the fast and slow contributions comparable. For atomic counterions, where the EFG is of intermolecular origin, the local motion contribution $\langle \chi^2 \rangle \tau_f$ and the residual QCC $\langle \chi \rangle$ depend markedly on the molecular details of the interface region, but in a way that is not readily captured by simple models.

3.2 Surfactant Molecules

Rotational isomerization in surfactant alkyl chains is too fast (< 10 ps) to produce a dispersion in the ^2H or ^{13}C relaxation.^{8,28} This introduces a certain model dependence in the interpretation,^{28–30} although constraints are imposed by the individual bond order parameters deduced from static dipole or quadrupole couplings.⁸ On a longer timescale (typically, 0.1–1 ns), the conformationally averaged surfactant molecule undergoes restricted reorientation within the aggregate. This motion can produce a high-field dispersion in the ^{13}C relaxation (which involves the Larmor frequency of ^1H), whereas the ^2H relaxation is usually in the extreme narrowing limit.²⁸ The relaxation anisotropy is expected to be weak for alkyl chain nuclei, but can be substantial for headgroup nuclei in double-chain surfactants.²⁸ The overall motion of surfactants is usually modeled as rotational diffusion of a symmetric top in a uniaxial potential of mean torque (see *Liquid Crystalline Samples: Relaxation Mechanisms*).

The relaxation of a surfactant nucleus induced by the intermolecular dipole coupling with a nuclear or electron spin in a counterion can, in certain cases, provide information about

Table 3 Relaxation Processes in Amphiphilic Liquid Crystals

Dynamics	Order fluctuations	Director fluctuations
Single-molecule	Diffusion in order gradient	Diffusion on curved interface Diffusion in nematic director field
Collective	Critical fluctuations	Micelle reorientation Nematic director fluctuations Interface shape fluctuations

the spatial distribution of the surfactant nucleus with respect to the interface.^{8,31} The interpretation of such relaxation data is, however, strongly model dependent.³²

4 MICROSTRUCTURE AND DIFFUSION

4.1 Fluctuating Local Anisotropy

Much of the intricate spin relaxation behavior of complex fluids such as amphiphilic liquid crystals can be rationalized in terms of a unifying concept: the fluctuating local anisotropy. On longer timescales, the net effect of the fast, local motions (see Section 3) is to project the quadrupole (or dipole–dipole) interaction tensor onto an axis, the (local) director, which usually coincides with the local interface normal. The motionally averaged, or projected, interaction tensor is proportional to the second-rank ordering tensor $\mathbf{S}$, with three independent components in the usual case of local uniaxial symmetry. In the director frame, $\mathbf{S}$ is diagonal and the three independent variables are the principal order parameter S and the set Ω of two angles that specify the director orientation (with respect to the crystal axes).

All relaxation processes, apart from the local motions, can be classified as either local order fluctuations, which modulate the order parameter $S(t)$, or local director fluctuations, which modulate the director orientation $\Omega(t)$. Each of these classes can be further subdivided according to whether the fluctuations are due to single-molecule dynamics (translational diffusion) or to collective processes, involving many molecules. Among the relaxation processes listed in Table 3, those in the director fluctuation class are generally most important. Diffusion of water or counterions between interface ($S \neq 0$) and bulk ($S = 0$) regions³³ is usually an inefficient relaxation process,^{21,34} and critical order fluctuations³⁵ occur only near phase transitions.

4.2 Diffusion on Curved Interfaces

All amphiphilic liquid crystalline phases, save the lamellar one, are built from curved interfaces, over which surfactants

and counterions diffuse freely. (The long-range Coulomb interaction effectively reduces the dimensionality of the diffusion space for counterions to two.^{21,33,34}) This constitutes an efficient relaxation process of the director fluctuation type, which can yield quantitative information about the interface geometry (microstructure) and the surface diffusion coefficient, D_s . Typically, the microstructure involves radii of curvature of the order 1–2 nm, while $D_s \approx (0.1–1) \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$. The associated correlation times are thus in the 1–10 ns range, which places the relaxation dispersion in the conventional MHz range of Larmor frequencies. We now consider how surface diffusion induced quadrupolar spin relaxation can be exploited in the various phases.

4.3 Hexagonal Phases

The normal hexagonal phase is built from cylindrical surfactant aggregates of indefinite length, arranged on a two-dimensional hexagonal lattice. Since the director, i.e. the cylinder surface normal, is everywhere perpendicular to the sixfold symmetry axis of the phase, surface diffusion around the cylinder contributes to only one of the three CFSDs, i.e.

$$J_{nn}^C(k\omega_0) = J_{\text{loc}} + \delta_{n2} \langle \chi \rangle^2 \frac{3}{8} \frac{\tau_s}{1 + (k\omega_0\tau_s)^2} \quad (8)$$

with the correlation time $\tau_s = R^2/(4D_s)$, and R the diffusion radius. In addition, the adiabatic ($k = 0$) CFSDs have contributions from long-wavelength cylinder undulations.

With R obtained from the X-ray Bragg spacing, the surface diffusion coefficients D_s of surfactants and counterions can be accurately ($\pm 10\%$) determined from the nonadiabatic ($k = 1, 2$) CFSDs obtained from the nonsecular relaxation anisotropy (see Figure 1) at a single magnetic field.^{20,36} In reversed hexagonal phases, the radius of the aqueous cylinders can be varied in a controlled way, allowing a direct verification of the R^2 scaling of the correlation time.³⁴

4.4 Lamellar Phases

In a classical lamellar phase, with periodically stacked, planar surfactant bilayers of indefinite lateral extent, one expects neither anisotropy nor dispersion in the nonsecular LFSDs, since in the absence of interface curvature, $J_{nn}^C(k\omega_0) = J_{\text{loc}}$ for $k = 1, 2$. (The secular LFSD, however, should exhibit anisotropy due to long-wavelength bilayer undulations; see Section 5.3). Spin relaxation is therefore a sensitive curvature probe for lamellar phases; any deviation from the classical microstructure is unambiguously revealed by the relaxation anisotropy and dispersion produced by molecular diffusion over curved interfaces.

In the lamellar phase of the sodium dodecyl sulfate/decanol/water system, the ^{23}Na relaxation (see Figure 1) provides direct evidence for a highly curved interface at low decanol content,²¹ whereas at higher decanol content the microstructure is classical. The relaxation behavior is consistent with a microstructure of ribbon-like aggregates, arranged on the smectic planes so as to preserve the uniaxial symmetry of the lamellar phase. The three CFSD functions $J_{nn}^C(\omega)$ can then be related to two irreducible (D_{2h}) ribbon-frame spectral density functions associated with surface diffusion around the ribbon-like aggregate.

4.5 Uniaxial Nematic Phases

Two types of uniaxial nematic phase occur in amphiphilic systems:⁴ the calamitic (N_C) and discotic (N_D) phases, built from orientationally ordered nonspherical micellar aggregates of approximately prolate and oblate spheroidal shape, respectively. To understand these phases, one needs to quantify the size of the micelles and their long-range orientational order.

Nuclear spin relaxation studies can, in principle, yield the micelle dimensions as well as the second-rank nematic order parameter.³⁷ Two difficulties are encountered, however. First, the fast magnetic alignment of nematic fluids precludes relaxation anisotropy measurements with conventional methods. This experimental problem can be partly overcome by sample spinning techniques (see *Spinning Liquid Crystalline Samples*). The second difficulty is intrinsic: spin relaxation is induced not only by molecular diffusion over the micelle surface, but also by rotation of the micelle around its symmetry axis and restricted tumbling of this axis. While the three CFSDs associated with spheroidal surface diffusion and single-micelle reorientation (in a uniaxial potential of mean torque) can be accurately calculated,³⁸ it is more difficult to describe the cooperative reorientation modes in the transition zone between the single-micelle and viscoelastic continuum behaviors (see Section 5.2). However, in the frequency range (typically > 10 MHz) where the cooperative modes are unimportant, quadrupolar relaxation of counterion and surfactant nuclei can yield useful, albeit somewhat model-dependent, information about micelle size and nematic order.^{37,39}

4.6 Cubic Phases

According to the topology of their microstructure, amphiphilic cubic phases are either of the micellar type with a three-dimensional periodic arrangement of nonspherical surfactant aggregates, or of the bicontinuous type with both aqueous and nonpolar regions connected over macroscopic distances in all three dimensions.⁵ In both types of cubic phase, surface diffusion is the major relaxation process. For micellar cubic phases, the spectral densities can be calculated as for nematic phases, also including molecular exchange between differently oriented micelles.⁴⁰

The microstructure of bicontinuous cubic phases is usually modeled in terms of certain triply periodic minimal surfaces. Due to the high symmetry of these surfaces, the surface-diffusion spectral densities should be nearly Lorentzian (as for diffusion on a sphere). The effective correlation times can then be expressed as⁴¹

$$\tau_s = -\frac{1 - cQ}{6D_s\langle K \rangle} \quad (9)$$

with c a numerical constant, Q the fourth-rank cubic order parameter, and $\langle K \rangle$ the (negative) average Gaussian curvature of the minimal surface, related via the Gauss–Bonnet theorem to the unit cell surface area and topology (Euler–Poincaré characteristic). The correlation time τ_s decreases strongly with increasing topological complexity and can therefore, in contrast to X-ray diffraction, distinguish among different microstructures that belong to the same crystallographic space group.⁴¹

The quadrupolar relaxation dispersion of surfactant chain and headgroup nuclei has been used to determine micelle dimensions in cubic phases.^{42,43} Since only powder samples of cubic phases have been studied so far,^{25,42,43} the full model-independent information content of the relaxation has not been extracted. Although sometimes referred to as the ‘viscous isotropic phase’, the cubic phase has an inherently anisotropic relaxation behavior (see Section 2.4) and the two irreducible CFSDs can be determined from single crystal relaxation data.⁴⁰

4.7 Low-Symmetry Phases

Although attractive with regard to their rich model-independent information content (see Table 2), amphiphilic phases of lower than hexagonal symmetry have not yet been subjected to spin relaxation studies. The four irreducible CFSDs from triply periodic tetragonal and rhombohedral phases might be analyzed in terms of surface diffusion on minimal surfaces, as for bicontinuous cubic phases. For two-dimensional rectangular phases, the ribbon-frame spectral densities discussed in Section 4.4 should be appropriate. Biaxial nematic phases pose a greater challenge however, in view of the large number of model parameters needed to describe surface diffusion on biaxial micelles undergoing asymmetric-top reorientation in a biaxial potential of mean torque.

5 LONG-WAVELENGTH DIRECTOR FLUCTUATIONS

5.1 General Considerations

For noncubic phases, spin relaxation in the sub-MHz frequency range is usually dominated by slow director fluctuations. The actual dynamic process inducing spin relaxation can be either long-range molecular diffusion or the intrinsic dynamics of collective modes. The theory of spin relaxation due to such processes is based on a phenomenological continuum description of liquid crystal mechanics, carried to second order in the elastic deformations.⁴⁴ The relaxation theory has so far been developed only for the uniaxial nematic and lamellar phases. Information about long-wavelength director fluctuations is contained in the anisotropic, secular LFSD $J_{00}^L(0; \beta)$ and in the low-frequency relaxation dispersion accessible by field cycling, echo train, and spin lock techniques (see Section 2.5).

5.2 Uniaxial Nematic Phases

The orientational state of a uniaxial nematic phase is specified at the continuum level by the director field $\mathbf{n}(\mathbf{r})$, where $\mathbf{n}$ is the unit vector along the principal axis of the micelle ordering tensor averaged over a macroscopically small volume of order λ_c^3 around the point $\mathbf{r}$. The three CFSDs involve time correlation functions of the transverse director components $\mathbf{n}_\perp = (n_x, n_y)$, which measure the orientational deviation of the director from the symmetry axis of the phase.

The CFSD $J_{11}^C(\omega_0)$, which is of second order in $n_\perp$, has a complicated dispersion with three regimes (equations (10a)–(10c)):

$$J_{11}^C(\omega_0) = \alpha_N \frac{\xi_m}{D_e} \left[1 - \left(\frac{\omega_0}{2\omega_m} \right)^{1/2} \right], \quad \omega_0 \ll \omega_m \quad (10a)$$

$$J_{11}^C(\omega_0) = \frac{\alpha_N}{(2D_e\omega_0)^{1/2}}, \quad \omega_m \ll \omega_0 \ll \omega_c \quad (10b)$$

$$J_{11}^C(\omega_0) = \alpha_N \frac{(4\pi)^2 D_e}{\lambda_c^3 \omega_0^2}, \quad \omega_c \ll \omega_0 \quad (10c)$$

with $\alpha_N = \frac{3}{4}\pi \langle \chi \rangle^2 k_B T / K$, $D_e = D + K/\eta$, K and η the effective curvature-elasticity and viscosity of the nematic fluid,⁴⁴ and D the long-range diffusion coefficient of the spin-bearing species. Further, $\omega_c = D_e (2\pi/\lambda_c)^2$ and $\omega_m = D_e/\xi_m^2$, with $\xi_m = \sqrt{\mu_0 K \Delta \chi} / B_0$ the magnetic coherence length.⁴⁴ Since, in amphiphilic nematic phases, $\omega_c/2\pi$ is typically of order 1 MHz, the classical⁴⁵ $1/\sqrt{\omega_0}$ dispersion regime in equation (10b) is accessible only with special techniques such as field cycling. In the conventional MHz range, only the high-frequency $1/\omega_0^2$ tail contributes to the relaxation (at < 10 MHz). In this frequency range, however, the theory may be inaccurate since short-wavelength (of order λ_c) continuum modes and single-micelle restricted tumbling modes make comparable contributions.

In the presence of a magnetic field, a stationary nematic sample (of thickness $\gg \xi_m$) adopts either a parallel or a perpendicular phase orientation with respect to the field. According to equation (5), the secular LFSD then involves only the CFSDs $J_{00}^C(0)$ and $J_{22}^C(0)$. Since these are of fourth order in $n_\perp$, the rates of molecular diffusion (D) and viscoelastic mode relaxation (K/η) are no longer additive.⁴⁶ For the case $D \gg K/\eta$ which usually applies to counterions, the result is⁴⁶

$$J_{00}^C(0) = 3J_{22}^C(0) = \langle \chi \rangle^2 \left(\frac{3k_B T}{4\pi K} \right)^2 \frac{1}{D} [\ln(2\pi \xi_m/\lambda_c) - 1.119] \quad (11)$$

The secular LFSD can thus be used to determine either the curvature-elasticity K or the long-range diffusion coefficient D .⁴⁶

The second-order adiabatic CFSD $J_{11}^C(0)$ in equation (10) can be obtained from relaxation studies at oblique phase orientations, achievable by sample spinning techniques. Two complications then arise. First, the magnetic field breaks the intrinsic uniaxial symmetry of the nematic phase, thus altering the low-frequency ($\omega_0 < \omega_m$) relaxation behavior.⁴⁷ Due to the orientation-dependent magnetic quenching of long-wavelength elastic fluctuation modes, the relaxation anisotropy involves CFSDs $J_{np}^C(0)$ with $n \neq p$, and hence no longer obeys equation (5).⁴⁷ (equation (10a) and equation (11) are strictly valid only for parallel alignment.) Second, since $J_{11}^C(0)$ exceeds $J_{00}^C(0)$ by a factor $\xi_m K/k_B T$ of order 10^3 , the conventional perturbation theory of spin relaxation may break down.

5.3 Lamellar Phases

Due to its layered microstructure, the lamellar phase differs fundamentally from a nematic fluid in its mechanical properties. Since the orientation of the bilayer normal (the director) is coupled to the position of the bilayer, director fluctuations in lamellar phases are suppressed not only by the bending rigidity of the bilayers but also by the (osmotic) forces that maintain the bilayer spacing. The continuum-mechanical description of the lamellar phase thus involves two elastic constants:⁴⁴ the splay-curvature modulus K_1 and the osmotic compression modulus $\bar{B}$. These are related to the average bilayer spacing d , the bilayer bending rigidity κ , and the curvature $V''(d)$ of the bilayer interaction as: $K_1 = \kappa/d$ and $\bar{B} = d V''(d)$. The lateral orientational correlation length $\xi_p = (d^2 K_1/\bar{B})^{1/4}$, also called the patch length, defines the crossover from a short-wavelength regime with independent bilayer fluctuations to a long-wavelength regime with highly coupled bilayer fluctuations. Since interbilayer forces limit the amplitude of long-wavelength fluctuation modes, magnetic quenching is unimportant in lamellar phases.

As in the nematic case, the dispersion of the second-order CFSD $J_{11}^C(\omega_0)$ exhibits three regimes (equations (12a)–(12c)):⁴⁸

$$J_{11}^C(\omega_0) = \alpha_L \frac{\xi_p^2}{D_e} \left[\ln \left(\frac{d}{L_z} + \frac{\omega_0}{\omega_p} \right)^{-1} + \frac{\omega_0}{\omega_p} \right], \quad \omega_0 \ll \omega_p \quad (12a)$$

$$J_{11}^C(\omega_0) = \alpha_L \frac{\pi}{\omega_0}, \quad \omega_p \ll \omega_0 \ll \omega_a \quad (12b)$$

$$J_{11}^C(\omega_0) = \alpha_L \frac{2\pi^2 D_e}{a^2 \omega_0^2}, \quad \omega_a \ll \omega_0 \quad (12c)$$

with $\alpha_L = (3/16\pi) \langle \chi \rangle^2 k_B T / \kappa$, $D_e = D_\perp + K_1/\eta$, $\omega_a = D_e(\pi/a)^2$, and $\omega_p = D_e \pi / \xi_p^2$. Further, L_z is the sample thickness and a is a lateral cut-off length, with a^2 of the order of the surfactant cross-section.

The adiabatic CFSD $J_{11}^C(0)$ is proportional to $\langle u^2 \rangle$, with u the vertical bilayer displacement, and hence exhibits a logarithmic divergence with sample size, characteristic of one-dimensional crystals.⁴⁴ At frequencies $\omega_0 \gg \omega_p$, $J_{11}^C(\omega_0)$ reflects independent bilayer fluctuations and the range $\omega_p \ll \omega_0 \ll \omega_a$ corresponds to the classical $1/\omega_0$ dispersion regime,⁴⁹ where $J_{11}^C(\omega_0)$ depends neither on the inter-bilayer forces (ξ_p) nor on the fluctuation rate (D_e). Since ξ_p is generally of the same order as the bilayer spacing d , $\omega_p/2\pi$ is of order 10 MHz for typical lamellar phases (but lower for very dilute samples). The experimentally accessible low-frequency dispersion (see Section 2.5) then reflects coupled bilayer fluctuations and can thus, like the adiabatic CFSD $J_{11}^C(0)$, provide information about inter-bilayer forces.

1 INTRODUCTION

In the beginning of the 1960s, NMR spectroscopists started to look for means to orient molecules with a particular goal in mind, i.e. to find a situation where the intermolecular direct dipolar couplings would average out whereas the corresponding intramolecular couplings would average to a nonzero value. Various methods were tried until, in 1963, Saupe and Englert¹ proposed that the sought-after properties can be reached by using liquid crystals as solvents.

The anisotropic orientational distribution of solute molecules in liquid crystals makes it possible to use the NMR observables (anisotropic couplings including both the direct dipole–dipole couplings and a contribution from the anisotropy of the indirect spin–spin coupling tensor, chemical shifts, and nuclear quadrupole splittings) for the determination of molecular structures, the anisotropies of nuclear shielding and spin–spin couplings, and quadrupole couplings for nuclei with spin ≥ 1 . In principle, the method is quite straightforward but in practice some complications may appear. In particular, the determination of molecular structures necessitates the introduction of the vibrational² and deformational^{3–5} corrections (see *Structure of Rigid Molecules Dissolved in Liquid Crystalline Solvents*). Since the anisotropic contribution of the spin–spin coupling tensor can only be separated from the experimental coupling when the direct dipole–dipole coupling is known, the corresponding effects have also to be considered here. To obtain reliable shielding anisotropies for protons and for nuclei with small anisotropy in general, various disturbing effects on the experimentally determined chemical shifts, such as local anisotropy due to solvent molecules, have to be taken into account.

A comprehensive review on the anisotropies of shielding and spin–spin coupling tensors determined using liquid crystalline solvents appeared in 1982.⁶ Since then, however, remarkable progress has taken place. This concerns spin–spin coupling anisotropy, in particular, where the inclusion of the deformational corrections leads to unambiguous, solvent independent results.

The NMR spectra observable from the spin- $\frac{1}{2}$ nuclei in molecules dissolved in liquid crystals resemble those in

isotropic liquids; relatively sharp, well resolved lines can be detected. Hence, analyses of spectra taken in the two phases are, in principle, similar (see *Liquid Crystalline Samples: Spectral Analysis*, and *Analysis of High-Resolution Solution State Spectra*). There are, however, also a few basic differences. Firstly, the anisotropic couplings between magnetically and chemically equivalent nuclei affect the structure of the spectrum. Thus, for example, the ^1H NMR spectrum of three methyl protons is a triplet and the six benzene protons give a spectrum very rich in resonance lines. Secondly, the dipole–dipole coupling constants are often large, of the order of kHz, and consequently the first-order approximation can usually be carried out only when the coupled nuclei are of different species.

2 LIQUID CRYSTALS

The liquid crystals most applicable in NMR spectroscopy are the thermotropic ones which have mesophases within certain temperature ranges.⁷ In a few cases, lyotropic liquid crystals have also been used. They are formed by mixing, for example, alkyl sulfates and the corresponding alcohols, sodium sulfate, and water.⁸

Thermotropic liquid crystals which are mainly used as solvents in NMR spectroscopy, can be classified into two main categories; nematic (N) and smectic (S). In the nematic phases, the molecules have only a short range positional order. However, if the liquid crystals consist of elongated molecules, as those used in the applications described in this context usually do, they tend to align with their long axes parallel to a common axis which defines the director (often called also the optic axis), $\mathbf{n}$, of the liquid crystal. The nematic phases are almost in all known cases uniaxial (rotational symmetry exists around the director) and apolar (the directions $\mathbf{n}$ and $-\mathbf{n}$ are equivalent). In the smectic phases the liquid crystal molecules possess long range order. A specific feature of smectic phases is the appearance of one-dimensional density waves or, as often called, layered structures. Smectic phases are divided into subgroups of which the smectic A phase (S_A) is the one used in the present applications. In this phase, the director coincides with the normal of the layer, and $\mathbf{n}$ and $-\mathbf{n}$ are equivalent. The structures of the nematic and smectic A phases are shown in Figure 1.

When a liquid crystalline sample is placed in an external magnetic field $\mathbf{B}$, the sample is magnetized so that the magnetization $\mathbf{M}$ is given by

$$M_\alpha = \mu_0^{-1} \chi_{\alpha\beta} B_\beta \quad (1)$$

Figure 1 Structures of thermotropic nematic (N) and smectic A (S_A) liquid crystalline phases. The direction of the director is shown by $\mathbf{n}$

2 ANISOTROPY OF SHIELDING AND COUPLING IN LIQUID CRYSTALLINE SOLUTIONS

where μ_0 is the permeability in vacuo and the $\chi_{\alpha\beta}$'s are elements of the diamagnetic (volume) susceptibility tensor, χ_m , which is diagonal in uniaxial phases.

The energy density, ρ_B , due to the magnetization $\mathbf{M}$ is:

$$\rho_B = - \int_0^B \mathbf{M} \cdot d\mathbf{B} = - \frac{B^2}{2\mu_0} \left[\chi_m + \frac{2}{3} \Delta\chi_m P_2(\cos \theta) \right] \quad (2)$$

where $\chi_m = \frac{1}{3} \text{Tr} \chi_m$ is the isotropic susceptibility, $\Delta\chi_m$ is the anisotropy of the susceptibility tensor, and $P_2(\cos \theta) = \frac{1}{2}(3 \cos^2 \theta - 1)$ is the second Legendre polynomial (θ being the angle between $\mathbf{B}$ and $\mathbf{n}$). Considering the condition of minimum energy density, one can conclude the following:

1. When $\Delta\chi_m$ is positive, ρ_B reaches a minimum with $P_2(\cos \theta) = 1$, i.e. the director is oriented parallel with the external magnetic field.
2. When $\Delta\chi_m$ is negative, ρ_B reaches a minimum with $P_2(\cos \theta) = -\frac{1}{2}$, i.e. when the director is oriented perpendicular to the external field.

Both types of thermotropic liquid crystals exist and have been used in studies of the properties of solute molecules. Furthermore, proper mixtures of liquid crystals with opposite signs of diamagnetic anisotropies have been utilized. (See *Liquid Crystals: Mixed Magnetic Susceptibility Solvents*.)

3 THE HAMILTONIAN OPERATOR AND OBSERVABLES

When considering the NMR spectra of spin- $\frac{1}{2}$ nuclei in molecules partially oriented in liquid crystals, the transition frequencies are dependent upon the nuclear shielding tensor, σ_i , the indirect spin-spin coupling tensor, $\mathbf{J}_{ij}$, and the direct dipole-dipole coupling tensor, $\mathbf{D}_{ij}$ (see *Liquid Crystals: General Considerations*). Then the total Hamiltonian operator is (in energy units):

$$\hat{\mathcal{H}} = -\hbar \sum_i \gamma_i \hat{\mathbf{I}}_i \cdot (\mathbf{1} - \sigma_i) \cdot \mathbf{B} + \hbar \sum_{i < j} \hat{\mathbf{I}}_i \cdot (\mathbf{J}_{ij} + \mathbf{D}_{ij}) \cdot \hat{\mathbf{I}}_j \quad (3)$$

where $\hbar$ is Planck's constant divided by 2π , γ_i is the magnetogyric ratio of nucleus i , and $\mathbf{1}$ is the unit tensor. On the basis of perturbation theory one can conclude that the terms of the Hamiltonian operator which do not commute with the total spin component, $\hat{I}_z$, in the direction of $\mathbf{B}$ (defined as the z direction of the laboratory frame) can be safely neglected. Furthermore, taking the time average of the observables over the anisotropic molecular tumbling, the operator shown in equation (3) can be approximated by:

$$\begin{aligned} \hat{\mathcal{H}} = & -\hbar \sum_i \gamma_i (1 - \sigma_i) B \hat{I}_{iz} \\ & + \hbar \sum_{i < j} J_{ij} \left[\hat{I}_{iz} \hat{I}_{jz} + \frac{1}{2} (\hat{I}_{i+} \hat{I}_{j-} + \hat{I}_{i-} \hat{I}_{j+}) \right] \\ & + \hbar \sum_{i < j} (2D_{ij} + J_{ij}^{\text{aniso}}) \left[\hat{I}_{iz} \hat{I}_{jz} - \frac{1}{4} (\hat{I}_{i+} \hat{I}_{j-} + \hat{I}_{i-} \hat{I}_{j+}) \right] \end{aligned} \quad (4)$$

In the operator shown in equation (4), the shielding is represented as

$$\begin{aligned} \sigma_i = \langle \sigma_{izz} \rangle &= \frac{1}{3} \sum_{\alpha} \sigma_{i\alpha\alpha} + \frac{2}{3} \left(\sum_{\alpha, \beta} S_{\alpha\beta} \sigma_{i\alpha\beta} \right) P_2(\cos \theta) \\ &= \sigma_i^{\text{iso}} + \sigma_i^{\text{aniso}} \end{aligned} \quad (5)$$

The isotropic spin-spin coupling constant, J_{ij} , and the anisotropic contribution, J_{ij}^{aniso} , are

$$J_{ij} = \frac{1}{3} \sum_{\alpha} J_{ij\alpha\alpha} \quad (6)$$

and

$$J_{ij}^{\text{aniso}} = \left(\frac{2}{3} \sum_{\alpha, \beta} S_{\alpha\beta} J_{ij\alpha\beta} \right) P_2(\cos \theta) \quad (7)$$

In equations (5)–(7), $\sigma_{i\alpha\beta}$ and $J_{ij\alpha\beta}$ are the elements of the shielding and spin-spin coupling tensor, respectively, in the molecule fixed coordinate system while the $S_{\alpha\beta}$ terms in turn, are the elements of the Saupe ordering tensor⁹ which are defined as

$$S_{\alpha\beta} = \frac{1}{2} \langle 3 \cos \theta_{\alpha n} \cos \theta_{\beta n} - \delta_{\alpha\beta} \rangle \quad (8)$$

where $\theta_{\alpha n}$ is the angle between the director $\mathbf{n}$ and the α axis of the coordinate system, the $\langle \rangle$ brackets indicate a time average, and $\delta_{\alpha\beta}$ is the Kronecker delta. The dipole-dipole coupling constant, D_{ij} , appearing in the operator shown in equation (4) is defined (when the correlation of the molecular reorientational and vibrational motions is neglected) as

$$D_{ij} = - \frac{\mu_0 \hbar \gamma_i \gamma_j}{8\pi^2 r_{ij}^3} S_{ij} \quad (9)$$

where r_{ij} is the internuclear distance, and

$$S_{ij} = \frac{1}{2} \langle 3 \cos^2 \theta_{ijB} - 1 \rangle \quad (10)$$

is called the order parameter (with respect to the external magnetic field) of the axis passing through i and j , and θ_{ijB} is the angle between the ij direction and the magnetic field. Since the order tensor is traceless and symmetric, it consists of five independent elements which are usually chosen as S_{cc} , ($S_{aa} - S_{bb}$), S_{ab} , S_{ac} , and S_{bc} (a , b and c are the axes of the molecule fixed coordinate system). Utilizing the coordinate transformation equation

$$S_{ij} = \sum_{\alpha, \beta} \cos \theta_{ij\alpha} \cos \theta_{ij\beta} S_{\alpha\beta} \quad (11)$$

S_{ij} can be written as:

$$\begin{aligned} S_{ij} = & \left[\frac{1}{2} S_{cc} (3 \cos^2 \theta_{ijc} - 1) + \frac{1}{2} (S_{aa} - S_{bb}) (\cos^2 \theta_{ija} - \cos^2 \theta_{ijb}) \right. \\ & + 2S_{ab} \cos^2 \theta_{ija} \cos^2 \theta_{ijb} + 2S_{ac} \cos^2 \theta_{ija} \cos^2 \theta_{ijc} \\ & \left. + 2S_{bc} \cos^2 \theta_{ijb} \cos^2 \theta_{ijc} \right] P_2(\cos \theta) \end{aligned} \quad (12)$$

The number of the independent elements of the order tensor can be reduced by taking into account molecular symmetry. The values of the order tensor elements are obtained from the dipole-dipole coupling constants provided that at least one internuclear distance is known.

4 SHIELDING ANISOTROPY

For a moment let us forget the complications that may occur particularly when determining small anisotropies of nuclear shieldings, and concentrate on the principles of how the shielding anisotropy is obtained from an NMR spectrum of a molecule partially oriented in a liquid crystal. Let us choose as an example a molecule possessing at least a

threefold symmetry axis, e.g. acetonitrile (CH_3CN). In such a case, the molecular orientation is completely determined by one order tensor element. Thus the experimental chemical shift, δ^{exp} , can be expressed in the form (note that δ increases to high frequency whereas σ increases to low frequency; for simplifying notations the subscript i will be omitted):

$$\begin{aligned}\delta^{\text{exp}} &= \delta^{\text{iso}} - \frac{2}{3} \left[\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) \right] S P_2(\cos \theta) \\ &\equiv \delta^{\text{iso}} - \frac{2}{3} \Delta\sigma S P_2(\cos \theta)\end{aligned}\quad (13)$$

where $\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) \equiv \Delta\sigma$ is the anisotropy of the shielding tensor [(x, y, z) is a molecule fixed coordinate system] and S is the order parameter of the molecular symmetry axis (which in the case of acetonitrile lies along the $-\text{C}\equiv\text{N}$ direction). Equation (13) contains two unknown parameters δ^{iso} and $\Delta\sigma$; the order parameter S is obtained from the experimental dipole-dipole couplings [defined in equation (9)] which do not contain an anisotropic contribution, J_{ij}^{aniso} , and are corrected for harmonic vibrations and preferably also for deformational contributions. Usually couplings of the type D_{HX} with ^1H as a coupling partner (D_{HH} in CH_3CN) are a safe choice.

The shielding anisotropy can be determined by changing either S or $P_2(\cos \theta)$. There exist several possibilities for both. They are described below.

4.1 Use of Isotropic-Nematic Phase Transitions

In this method, $\delta^{\text{iso}} = \delta^{\text{exp}}(\text{isotropic})$ is determined in the liquid crystal heated to the isotropic state (when $S \equiv 0$) and assumed not to be affected by the change of phase. Then the sample is cooled to the nematic state and $\delta^{\text{exp}}(\text{nem.})$ is measured. Consequently,

$$\Delta\sigma = -\frac{3}{2} \left[\frac{\delta^{\text{exp}}(\text{nem.}) - \delta^{\text{exp}}(\text{isotropic})}{S P_2(\cos \theta)} \right] \quad (14)$$

4.2 Gradient Method

One disadvantage of the previous method is that the experiments have to be carried out at two different phases, isotropic and nematic. This can be avoided by working exclusively in a nematic or smectic phase and changing the molecular degree of order, i.e. the order parameter S . This is achieved by changing the temperature or concentration of the sample. When δ^{exp} is expressed graphically as a function of $S P_2(\cos \theta)$, the slope of the resulting straight line gives $\Delta\sigma$ and the intercept δ^{iso} .

4.3 Use of Smectic Phases

The smectic A phases of thermotropic liquid crystals often possess the property that once oriented in a magnetic field they keep the orientation for a long time. This makes it possible to change in a very straightforward way the angle between the director $\mathbf{n}$ and the magnetic field $\mathbf{B}$, i.e. the factor $P_2(\cos \theta)$ in equation (13), while S remains unchanged.¹⁰ The

shielding anisotropy is then obtained without changing solvent properties.

When the liquid crystal is heated to the isotropic state and then cooled in the magnetic field to the smectic state, the director orients (when $\Delta\chi_{\text{m}} > 0$) along the magnetic field and $\theta = 0$. Thus

$$\delta^{\text{exp}}(0) = \delta^{\text{iso}} - \frac{2}{3} \Delta\sigma S \quad (15)$$

The rotation of the sample (in a conventional electromagnet) around the tube axis by 90° [generally, the rotation angle is obtained from the ratio of the dipolar couplings: $D_{ij}(\theta)/D_{ij}(0) = P_2(\cos \theta)$] gives:

$$\delta^{\text{exp}}(90) = \delta^{\text{iso}} + \frac{1}{3} \Delta\sigma S \quad (16)$$

and consequently,

$$\Delta\sigma = \frac{\delta^{\text{exp}}(90) - \delta^{\text{exp}}(0)}{S} \quad (17)$$

In the smectic phases the degree of solute molecular orientation is usually high, when both S and the chemical shift difference [nominator in equation (17)] are large, leading to a good relative precision in $\Delta\sigma$. Figure 2, which shows the ^{199}Hg NMR spectrum of dimethylmercury ($\text{CH}_3)_2\text{Hg}$ at the orientation described above, illustrates the method.

4.4 Use of Mixtures of Thermotropic Nematic Liquid Crystals

4.4.1 Liquid Crystals with Opposite Diamagnetic Anisotropy

This method, called NEMIX, is comparable with the one described in Section 4.3. When two thermotropic nematic liquid crystals possessing opposite anisotropies of diamagnetic susceptibility, $\Delta\chi_{\text{m}}$, are mixed at a certain critical concentration ratio ($\Delta\chi_{\text{m}}$ of the critical mixture is equal to 0), the 90°

Figure 2 ^{199}Hg NMR spectrum of dimethylmercury $[(\text{CH}_3)_2\text{Hg}]$ in the smectic A phase of HAB: 0° , director parallel with the external magnetic field, 90° , director perpendicular to the external magnetic field. (Reproduced with permission of Heyden & Sons from J. Jokisaari and P. Diehl²⁶)

Figure 3 The experimental chemical shift, δ_F^{exp} , of the ^{19}F nucleus and the order parameter of the C_3 symmetry axis, S , for methyl fluoride (CH_3F) as a function of the liquid crystal composition in mixtures of ZLI 1167 and EBBA. The mixtures used in the NEMIX and ENEMIX methods are indicated by N and E, respectively

rotation of the liquid crystal director is achieved by changing the sign of $\Delta\chi_m$ with the aid of a slight temperature change or a small temperature gradient over the sample volume (see *Liquid Crystals: Mixed Magnetic Susceptibility Solvents*). In the latter case, the NMR spectra corresponding to the two director orientations can be detected simultaneously.^{11,12} The shielding anisotropy can be calculated from equation (17). Figure 3 shows how the method works.

4.4.2 Liquid Crystals with Opposite Deformational Effects on Molecular Structure

The anisotropic forces that cause the orientation of solute molecules at the same time deform their structure leading to the solvent dependence of structure. It has appeared that ^{13}C -enriched methane ($^{13}\text{CH}_4$) is a convenient and practical reference, not only for chemical shifts but also for structural deformations. It has been found that in certain mixtures of thermotropic liquid crystals the methane molecule is not deformed.¹³ The components of the mixture may be selected so that they possess opposite diamagnetic anisotropies and, consequently, parallel and perpendicular orientations of the director with respect to the external magnetic field can be produced in a similar way to that discussed above. Figure 3 also demonstrates this method, which is called ENEMIX. In contrast to the NEMIX method and the method based on the utilization of smectic liquid crystals, the ratio of the S parameters corresponding to the two director orientations may not exactly equal -2 , whence

$$\Delta\sigma = -\frac{3}{2} \left[\frac{\delta^{\text{exp}}(0) - \delta^{\text{exp}}(90)}{S(0) - S(90)} \right] \quad (18)$$

4.5 Use of Sample Spinning

4.5.1 Sample Tube Axis Perpendicular to the Magnetic Field

As discussed above, the liquid crystals director orients either along the external magnetic field or perpendicular to it depending upon the sign of the diamagnetic anisotropy. In a conventional electromagnet, the director orients perpendicular to the tube axis (when $\Delta\chi_m > 0$; if $\Delta\chi_m < 0$ the director orients along the tube axis and no change in the orientation can be achieved by spinning the sample tube). When the sample is spinning around the tube axis the liquid crystal experiences a viscous torque

$$N_v = \lambda_1 \Omega \quad (19)$$

where Ω is the angular speed and λ_1 a coefficient proportional to the viscosity of the solution. The magnetic torque opposes the viscous torque, and in equilibrium $N_B = N_v$. Thus the angle θ_0 between the magnetic field and the director is determined by

$$\sin 2\theta_0 = -\frac{2\mu_0\lambda_1}{B^2\Delta\chi_m} \Omega \quad (20)$$

The value of $SP_2(\cos \theta_0)$ can be determined from the dipolar coupling constants and the shielding anisotropy calculated as in the previous method. On the other hand, θ_0 can be varied by varying the angular speed Ω . There is, however, an upper limit for Ω , the so-called critical speed, $\Omega_c = -B^2\Delta\chi_m/2\mu_0\lambda_1$, above which no equilibrium state can be reached but the director rotates with the tube. When the experimental chemical shift is plotted as a function of $SP_2(\cos \theta_0)$, the shielding

anisotropy is obtained from the slope of the resulting straight line.

4.5.2 Variable Angle Spinning

Let us consider a general case where the spinning axis of a sample tube forms an angle β with the magnetic field. Transforming the susceptibility tensor into the principal axis system rotating around the magnetic field direction and taking a time average,¹⁴ the magnetic energy density can be represented in the form

$$\langle \rho_B \rangle = -\frac{B^2}{2\mu_0} \left[\chi_m + \frac{2}{3} \Delta\chi_m P_2(\cos \beta) P_2(\cos \delta) \right] \quad (21)$$

where δ is the angle between the spinning axis and the liquid crystal director. From the condition of minimum energy density, one can conclude the following: (a) when $\Delta\chi_m > 0$ and $0 \leq \beta < \beta_m$ (β_m is the magic angle, 54.7°), the liquid crystal director orients parallel with the spinning axis, i.e. the angle between the director and the magnetic field equals β ; (b) when $\Delta\chi_m > 0$ and $\beta_m < \beta \leq \pi/2$, the directors are equally distributed in the plane perpendicular to the spinning axis; (c) when $\Delta\chi_m < 0$ and $0 \leq \beta < \beta_m$, the situation is similar to (b); and (d) when $\Delta\chi_m < 0$ and $\beta_m < \beta \leq \pi/2$, the situation is similar to (a).

The slope of the resulting straight line obtained by plotting the experimental chemical shift as a function of $SP_2(\cos \beta)$, or as a function of a dipolar coupling constant as shown in Figure 4, gives the shielding anisotropy.

4.6 Examples and Reliability of Results

4.6.1 Molecules Whose Orientation Can Be Described by One Order Parameter

Tables (1)-(3) show $\Delta\sigma$ values determined by applying various liquid crystals and methods described above. The examples are chosen so that they cover a wide range of values, and consequently yield the weaknesses on the one hand and the reliability on the other hand of liquid crystal NMR spectroscopy as applied to the determination of shielding anisotropies. Table 1 lists the proton shielding anisotropy values measured for acetonitrile (CH_3CN). As can be seen, they vary over a relatively wide range, and both positive and negative values have been reported. The $\Delta\sigma_{\text{H}}$ value seems to depend upon the method used, liquid crystal solvent, and reference method and substance. This is due to the fact that the measured shielding is affected by three different anisotropic contributions:

$$\sigma^{\text{exp}} = \sigma^{\text{mol}} + \sigma^{\text{local}} + \sigma^{\text{bulk}} \quad (22)$$

where σ^{mol} (the quantity of interest) arises from the electron distribution in the molecule, σ^{local} (the local effect) from the nearest neighbor molecules, and σ^{bulk} (the bulk effect) from the other parts of the sample. The greatest problem is caused by the local effects; obviously the solute and reference molecules do not probe exactly the same local fields, leading to an erroneous $\Delta\sigma$. Local effects in a smectic liquid crystal, and in mixtures of thermotropic nematic liquid crystals with opposite diamagnetic anisotropies, have been studied by using globular solutes (which do not orient in liquid crystals, i.e. $S = 0$) and found to be from -0.2 to -0.5 ppm for protons.¹⁵⁻¹⁷ These

Figure 4 Plot of δ^{exp} for the ^1H nucleus (referenced to internal TMS) as a function of D_{HH} for methyl iodide (CH_3I) in three liquid crystals: phase 4 ($\square$); ZLI 1167 (39.1%)/phase 4 (60.9%) ($\bullet$); and ZLI 1167 (57.6%)/phase 4 (42.4%) ($\times$). The data were produced on a VAS system by varying the angle between the spinning axis and the external magnetic field. The slope, κ , of the straight line yields the proton shielding anisotropy $\delta\sigma_{\text{H}} = (3/4) (K_{\text{HH}}/r_{\text{HH}}^3) \kappa$, where $K_{\text{HH}} = \mu_0 \hbar \gamma_{\text{H}}^2 / 8\pi^2$. (Reproduced with permission of Academic Press from T. Väänänen, J. Jokisaari, and M. Seläntaus³³). Note: the δ scale is opposite to the one used in the present text

experiments and the earlier ones^{18,19} mean that the anisotropic contribution of the local effects may be of the same magnitude as σ^{aniso} for protons, but also for other nuclei if their shielding anisotropy is not very large.

The first column of Table 2 shows that the shielding anisotropy of the methyl carbon, $\Delta\sigma_{\text{CH}_3}$ in acetonitrile, being of the order of 20 ppm, also depends markedly on the applied experimental method and liquid crystal solvent. On the contrary, the shielding anisotropies measured for the $-\text{C}\equiv\text{N}$ carbon, $\Delta\sigma_{\text{CN}}$, in acetonitrile as well as those for the ^{199}Hg nucleus in dimethylmercury $[(\text{CH}_3)_2\text{Hg}]$ (see Table 3) are virtually insensitive to all these factors. The small scatter arises from the internuclear distance chosen as a basis in calculating the order parameter S and from whether vibrational corrections are taken into account or not.

The experiments carried out until now and comparisons made with the values produced by other techniques or theoretical calculations provide strong support for the modified ENEMIX method giving the most reliable estimates for small $\Delta\sigma$ s.²¹

4.6.2 Molecules Whose Orientation Can Be Described by Two Order Parameters

In cases where molecules possess two perpendicular planes of symmetry as, for example, monosubstituted benzenes and heteroatomic five-membered rings, the experimental chemical shift can be represented in the form:

$$\delta^{\text{exp}} = \delta^{\text{iso}} - \frac{2}{3} \left\{ S_{zz} \left[\sigma_{zz} - \frac{1}{2} (\sigma_{xx} + \sigma_{yy}) \right] + \frac{1}{2} (S_{xx} - S_{yy}) (\sigma_{xx} - \sigma_{yy}) \right\} P_2(\cos \theta) \quad (23)$$

^bIGLO method with two different basis sets. Large basis set results on the right.

The shielding anisotropy, $\Delta\sigma = \sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy})$, and the difference $(\sigma_{xx} - \sigma_{yy})$ are obtained separately only if the ratio $(S_{xx} - S_{yy})/S_{zz}$ can be varied. Consequently, none of the methods described above which are based on the change of direction of the liquid crystal director with respect to the external magnetic field, i.e. the variation of the $P_2(\cos \theta)$ factor, is applicable here. The variation of the ratio $(S_{xx} - S_{yy})/S_{zz}$ may be produced by changing the sample temperature or by using different liquid crystal solvents. Then one has to assume that the shielding tensor elements are not affected by the experimental conditions.

The determination of the ¹³C shielding anisotropies in molecules which are large in the liquid crystal NMR scale (when the number of magnetic nuclei increases, the NMR spectrum of an oriented molecule becomes very complex; in practice the upper limit for the number of active, interacting nuclei is 10–12), and contain several carbon atoms and ¹³C in natural abundance, is usually at least very cumbersome if not impossible from the proton coupled spectra. Therefore, a method has been proposed which uses a spin echo sequence $[90^\circ - \tau - 180^\circ - 2\tau - 180^\circ - \tau - \text{acquisition}]$ and phase-alternated broadband decoupling.³⁰ The echo sequence cancels the possible overlap of the solute signals by the solvent signals.

Table 3 ¹⁹⁹Hg Shielding Anisotropy in Dimethylmercury Determined by Various Methods in Different Liquid Crystals. For Comparison, Results obtained from Spin–Lattice Relaxation Time Measurements are also Included

Figure 5 The ^{125}Te NMR spectrum of tellurophene ($\text{C}_4\text{H}_4\text{Te}$) in (a) ZLI 1167 (58%)/phase 4(42%), (b) EBBA and (c) ZLI 1167. (Reproduced with permission of Taylor & Francis from J. Jokisaari and T. Väänänen³¹)

The ^{13}C NMR spectrum yields the chemical shifts whereas the order parameters appearing in equation (23) are obtained from the ^1H spectrum.

The NMR spectroscopy of solute molecules in liquid crystals has not been applied very much to the investigations of shielding anisotropies of the so-called heavy nuclei. Most of the studies deal with the ^1H , ^{13}C , ^{19}F , and ^{31}P nuclei, and highly symmetrical molecules.⁶ This is somewhat surprising because the method is best when the shielding anisotropy is fairly large. There has been, however, some work carried out for ^{111}Cd , ^{113}Cd , and ^{199}Hg in molecules with C_3 symmetry, and one work for the ^{125}Te nucleus in a C_{2v} symmetric molecule, tellurophene ($\text{C}_4\text{H}_4\text{Te}$).³¹ The ^{125}Te NMR spectra of tellurophene in three liquid crystals are shown in Figure 5.

Equation (23) can be rewritten in the form

$$-\frac{3}{2} \left[\frac{\delta^{\text{exp}} - \delta^{\text{iso}}}{S_{zz}} \right] = \left[\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) \right] + \frac{\sigma_{xx} - \sigma_{yy}}{2} \frac{S_{xx} - S_{yy}}{S_{zz}} \quad (24)$$

Table 4 The Results of the ^{125}Te NMR Study of Tellurophene Dissolved in three Liquid Crystals.³¹ The Signs of δ^{exp} and δ^{iso} are Opposite to those in the Original Paper due to the Different Definition of the δ scale

Liquid crystal	δ^{exp} (ppm)	δ^{iso} (ppm) ^a	$(S_{xx} - S_{yy})/S_{zz}$ ^b	S_{zz} ^{b,c}
EBBA	2.50	-33.55	0.5033	0.0363
ZLI 1167/phase 4	48.51	-34.83	1.7478	0.0953
ZLI 1167	-85.02	-35.60	1.9992	-0.0592

The intercept of the straight line obtained by plotting the left hand side of equation (24) as a function of $(S_{xx} - S_{yy})/S_{zz}$ yields $[\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy})]$ whereas the slope gives $(\sigma_{xx} - \sigma_{yy})$. The results derived for ^{125}Te in tellurophene are collected in Table 4.

5 SPIN-SPIN COUPLING ANISOTROPY

The determination of reliable anisotropies, ΔJ_{ij} , of the spin-spin coupling tensors using NMR spectroscopy of molecules dissolved in liquid crystals may be a fairly difficult task. This is due to the fact that the experimental couplings, D_{ij}^{exp} , are dominated by the direct dipole-dipole coupling tensor elements, and moreover, in real molecules the dipole-dipole as well as spin-spin coupling tensors are averages over intramolecular motions. However, when performing proper analyses of data (sets of D_{ij}^{exp} values) preferably (often necessarily) produced in many liquid crystal solvents, most reliable and accurate ΔJ_{ij} values can be determined.

5.1 Quantitative Determination of J Anisotropy

The experimentally available couplings D_{ij}^{exp} can be expressed as a sum of several contributions (*Structure of Rigid Molecules Dissolved in Liquid Crystalline Solvents*):

$$D_{ij}^{\text{exp}} = D_{ij}^{\text{e}} + D_{ij}^{\text{ah}} + D_{ij}^{\text{h}} + D_{ij}^{\text{d}} + \frac{1}{2} J_{ij}^{\text{aniso}} \quad (25)$$

In equation (25), the first four terms on the right-hand side constitute the direct dipolar part of the coupling: D_{ij}^{e} is the dipole-dipole coupling corresponding to the equilibrium structure of the molecule; D_{ij}^{aff} is the contribution from the anharmonicity of the vibrational potential (the sum of these terms $D_{ij}^{\text{e}} + D_{ij}^{\text{ah}} = D_{ij}^{\alpha}$ is the dipole-dipole coupling corresponding to the so-called r_{α} structure of the molecule; the anharmonic force constants are often not available and thus only the r_{α} structure can be determined); D_{ij}^{h} is the contribution from the harmonic vibrations; and D_{ij}^{d} (the so-called deformational contribution which is responsible for the solvent dependence of structure) from the correlation between

$$\Delta\sigma = \sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) = -1569 \pm 21 \text{ ppm}$$

$$\sigma_{xx} - \sigma_{yy} = 307 \pm 26 \text{ ppm}$$

^aObtained from a sample heated to isotropic state.

^bDetermined from the ^1H - ^{125}Te dipolar couplings by assuming the corresponding J^{aniso} to be negligible.

^cWith respect to the external magnetic field.

vibrational and reorientational motions (time averages of S_{ij} and r_{ij}^{-3} appearing in the definition of the dipole–dipole coupling, equation (9), cannot be taken independently).

In order to get a reliable value for J_{ij}^{aniso} (which is normally small and in many cases comparable in magnitude with the vibrational and deformational correction terms), the molecular structure should be determined as completely as possible with the aid of the D_{ij}^{exp} values. This necessarily means a full analysis of data taking into account the interactions (the anisotropic forces that tend to orient molecules) between the solute and solvent molecules. In such an analysis the number of unknown parameters often exceeds the number of D_{ij}^{exp} values obtainable from one experiment, i.e. the problem becomes underdetermined. This increasing number of parameters is a consequence of the deformational effects. For example, in order to be able to calculate deformational corrections to J^{aniso} , one should know the derivatives of the spin–spin coupling tensor with respect to the vibrational normal coordinates. These are not available, and consequently must be used as adjustable parameters.³² The problem of underdetermination can, however, be overcome by carrying out experiments in several liquid crystalline solvents.

Another uncertainty in the determination of J_{ij}^{aniso} may appear in cases of spin systems consisting of different nuclear species, for instance I and S spins. Thus, the NMR spectrum yields only the sum $|2D_{is}^{\text{exp}} + J_{is}|$. If the spin–spin coupling constant, J_{is} , cannot be determined under the same experimental conditions (the same solvent, temperature, concentration, etc.) as the sum, an additional uncertainty is introduced into D_{is}^{exp} , and consequently, also into J_{is}^{aniso} . In principle, J_{is} can be determined in liquid crystalline phases by performing, for instance, VAS (Variable Angle Spinning) experiments.³³

Let us consider the determination of the anisotropy of the ^{13}C – ^{19}F spin–spin coupling in the methyl fluoride (CH_3F) molecule. Due to the C_3 symmetry of the molecule, its orientation can be described by one order parameter, S , of the symmetry axis. Then the anisotropic contribution to the experimental coupling $D_{\text{CF}}^{\text{exp}}$ can be expressed in the form:

$$J_{\text{CF}}^{\text{aniso}} = \frac{2}{3} \Delta J_{\text{CF}} S P_2(\cos \theta) \quad (26)$$

where $\Delta J_{\text{CF}} = J_{\text{CFzz}} - \frac{1}{2}(J_{\text{CFxx}} + J_{\text{CFyy}})$ is the anisotropy of the coupling tensor $\mathbf{J}_{\text{CF}}$. When the experimental dipolar couplings are corrected for harmonic vibrations but the deformational corrections are neglected, ΔJ_{CF} appears to be solvent dependent to a very great extent, as shown in Table 5. This large scatter of results is removed when all the dipolar couplings and $J_{\text{CF}}^{\text{aniso}}$ are corrected for deformational effects and a joint analysis of nine experiments (44 couplings, $D_{\text{CF}}^{\text{exp}}$ in one liquid crystal could not be obtained, and 23 parameters) is carried out. This analysis results in $\Delta J_{\text{CF}} = 404 \pm 31$ Hz. The relative anisotropy, $\Delta J_{\text{CF}}/J_{\text{CF}}$, is -2.50 ± 0.20 (J_{CF} appears to be slightly dependent upon the liquid crystal solvent, its average value is -161.43 Hz) and should be compared with -2.70 obtained by Hartree–Fock theory (ab initio) and by a semiempirical finite perturbation method at the INDO MO level of approximation.³⁴ The first-order polarization propagator approach has led to the ΔJ_{CF} value of 296.41 Hz.³⁵ Consequently, the experimental results of a joint analysis and the theoretical results are in fair agreement.

Reinforcement for the workability of the method is provided by the studies on acetonitrile (CH_3CN) and methyl isocyanide

Table 5 The Anisotropy ΔJ_{CF} of the ^{13}C – ^{19}F Spin–Spin Coupling Tensor for Methyl Fluoride ($^{13}\text{CH}_3\text{F}$) in Various Liquid Crystals. The Dipolar Couplings are Corrected for Harmonic Vibrations but not for Deformational Effects. The Result of the Joint Analysis (which takes into account also the Deformational Effects) of Nine Sets of D_{ij}^{exp} Values (44 Couplings and 23 Parameters) is also given for Comparison³²

(CH_3NC). Table 6 clearly shows that when the harmonic vibrational and deformational effects are taken into account in the experimental dipolar couplings, the ΔJ values are in nice accord with the theoretical ones.

5.2 Qualitative Revelation of J Anisotropy

Molecular symmetry can place very restrictive conditions for the ratios of dipolar coupling constants. Consequently, this can be used to reveal whether D^{exp} includes a contribution from J^{aniso} or not. If the examination of the ratios $D_{ij}^{\text{exp}}/D_{kl}^{\text{exp}}$ shows that they differ from the corresponding ratios of direct dipolar couplings ($D^{\text{dir}} = D^{\text{exp}} - \frac{1}{2}J^{\text{aniso}} = D^e + D^{\text{ah}} + D^{\text{h}} + D^{\text{d}}$, see equation (26)), they (or at least some of them) may be affected by J^{aniso} .

Benzene is a good example of a molecule in which symmetry completely fixes the ratios of the dipolar couplings. The order parameter of each ij direction equals $-\frac{1}{2}S$ (S is the order parameter of the sixfold symmetry axis) and consequently the following equation is valid:

$$\frac{D_{ij}^{\text{dir}}}{D_{kl}^{\text{dir}}} = \frac{\gamma_i \gamma_j}{\gamma_k \gamma_l} \left(\frac{r_{kl}}{r_{ij}} \right)^3 \quad (27)$$

It follows from the hexagonal symmetry of benzene that $r_m = \sqrt{3}r_o$ and $r_p = 2r_o$ ($o = \text{ortho}$, $m = \text{meta}$, $p = \text{para}$). Thus for the nuclei of same isotopic species, $D_o/D_m/D_p = 1 : \sqrt{3}/9 : 1/8 \sim 1 : 0.1925 : 0.1250$. It has been found that the ^1H – ^1H couplings in benzene indeed fulfil these ratios (in particular, when the experimental couplings are corrected for harmonic vibrational and deformational effects) and thus the $J_{\text{HH}}^{\text{aniso}}$ values are obviously negligible.⁴ In contrast, remarkable deviations have been detected for the ^{13}C – ^{13}C couplings (corrected for harmonic vibrations).³⁹

Equation (27) is not only valid for benzene but more generally. Thus, if S_{ij} for the nuclei i and j is the same as S_{kl} for the nuclei k and l , in other words the axes passing through

1 INTRODUCTION

Deuteron NMR spectroscopy (^2H NMR) is an extremely powerful technique for investigating molecular order and dynamics. The usefulness and uniqueness of this method lies in the wide range of timescales that are accessible for quantitative investigation. Fast molecular motion, with correlation times in the picosecond range, can be investigated by using relaxation rates to determine the orientation and temperature dependence of individual spectral density functions.¹ In the intermediate regime, processes with correlation times in the range $\tau_c \approx 10^{-4}$ – 10^{-8} s are characterized by motional narrowing effects on quadrupole echo lineshapes.² For slow motions, decay of quadrupolar order,³ selective inversion,⁴ or 2D exchange spectroscopy⁵ permit investigation of rotational dynamics with correlation times approaching the spin–lattice relaxation time, which can vary from milliseconds to several hundred seconds. This article is focused on describing ^2H NMR experiments which can be used to measure specific relaxation times, T_j , in oriented media. The primary motivation is to provide information which is essential to improving the understanding of molecular motion in thermotropic liquid crystals. Many experiments have been developed to measure different relaxation rates ($R_j = 1/T_j$); these will be summarized and their sensitivity to random and systematic errors will be considered.

The utility of ^2H NMR is enhanced by the fact that the dominant quadrupole interaction is both small enough to permit recording of undistorted spectra and sufficiently large to be a sensitive probe of local structure and dynamics. Dipolar interactions and associated many-body complications are usually negligible, and the interaction between the nuclear quadrupole moment and the local electric field gradient (EFG) tensor is described by a one-particle Hamiltonian. As a result the spin dynamics of deuterons, in realistically complicated systems, is simple enough to allow rigorous density matrix analysis of multiple pulse sequences and

relaxation behavior. This greatly facilitates the development of new NMR techniques and simplifies the interpretation of relaxation behavior, thereby providing stringent tests of theoretical descriptions of ordering and dynamics.

In discussing motion in ordered environments, it is necessary to distinguish between studies on nonmesogenic solutes dissolved in anisotropic fluids, and studies of the liquid crystal molecules themselves. Measurements of spin relaxation of small, rigid solute molecules can be interpreted without the uncertain approximations inherent in descriptions of internal motion, and provide useful tests for general theories of how an ordering potential affects the dynamic processes of small solutes. However, the weak ordering and fast motion of solutes make them unreliable probes of liquid crystal dynamics. An understanding of the basic physics of liquid crystals is better achieved through direct investigations of carefully chosen liquid crystalline materials.

In the nematic phase, the motion of liquid crystal molecules is assumed to be fast enough to be in the motional narrowing regime. Thus, the fluctuating Hamiltonian $\hat{\mathcal{H}}'(t)$ responsible for relaxation varies rapidly compared with precession under the static Hamiltonian $\hat{\mathcal{H}}_0$, i.e. the motion is fast compared with the rigid lattice linewidth. Under these circumstances, Redfield theory⁶ can be used to express the measured relaxation rates in terms of spectral densities of motion. The long-range order, which leads to a nonzero average value of the anisotropic quadrupole interaction, has profound effects on the motional spectral densities which govern spin relaxation. It is now well established that in the nematic phase, contributions to nuclear spin relaxation are made by restricted reorientation of individual molecules, internal rotations within the molecule, and by long-range quasi-coherent hydrodynamic modes such as order director fluctuations (ODFs).

In the more ordered liquid crystal phases, including smectics, lyotropics, and discotics, there is more uncertainty about the dominant motional processes. Spin relaxation studies can be used to help clarify the details of molecular dynamics in these systems. Throughout this article, Redfield theory will be used to describe the effects of molecular reorientation on spin relaxation. It should be appreciated that such motional narrowing approximations may not remain valid for these more complicated mesophases. For ultraslow motions, the concept of spectral densities is not sufficiently general to describe spin relaxation, and more rigorous approaches based on the stochastic Liouville equation must be used.

2 SPIN DYNAMICS

The time-independent Hamiltonian for a deuteron in an anisotropic environment is given by

$$\hat{\mathcal{H}}_0 = -\omega_0 \hat{I}_Z + \frac{1}{3} \omega_Q (3\hat{I}_Z^2 - \hat{\mathbf{I}} \cdot \hat{\mathbf{I}}) \quad (1)$$

Here $\omega_0 = 2\pi\nu_0$ is the Larmor frequency (in radians per second), $2\omega_Q = 4\pi\nu_Q$ is the quadrupole splitting, and $\hat{I}_Z$ is the operator for spin angular momentum about the space-fixed Z axis. Energy levels and transition frequencies associated with this Hamiltonian are illustrated in Figure 1. In isotropic liquids, where $\nu_Q = 0$, the two transitions are degenerate and occur at the Larmor frequency. In an oriented medium the quadrupolar

Figure 1 The energy level diagram for a spin-1 deuteron in a static magnetic field (left), and including the first-order quadrupolar interaction (right). Single quantum transition frequencies are indicated by vertical arrows on the diagram, and the corresponding NMR spectra are sketched

splitting between the $1 \rightarrow 2$ and $2 \rightarrow 3$ transitions ($2\nu_Q$) depends on the order parameters. Detailed discussions of the effects of orientational order on the NMR spectra of liquid crystals are available in the literature.^{7,8}

Relaxation of deuterons in an ordered medium is best described using density matrix formalism. In the Redfield limit, in the absence of rf irradiation, the spin density matrix element, $\rho_{ij}(t)$, for an ensemble of deuterons evolves according to the equation

$$\frac{\partial \rho_{ij}(t)}{\partial t} = i\omega_{ij}\rho_{ij} + \sum_{kl} R_{ijkl}[\rho_{kl}(t) - \rho_{kl}(\infty)] \quad (2)$$

Here $\omega_{ij} = (\omega_j - \omega_i)$ is the transition frequency between the eigenstates $|i\rangle$ and $|j\rangle$ of the time-independent spin Hamiltonian, the R_{ijkl} are elements of the Redfield relaxation supermatrix, and $\rho_{kl}(\infty)$ is element kl of the thermal equilibrium density matrix. There are two fundamentally different types of states of the density matrix: diagonal elements ($i = j$), which correspond to populations of the eigenstates, and coherences ($i \neq j$), which correspond to phase coherence in the wavefunctions of the eigenstates. For a single deuteron the off-diagonal density matrix elements include two single quantum coherences $\rho_{12}(t)$ and $\rho_{23}(t)$ with precession frequencies $\nu_{12} = (\Delta + \nu_Q)$ and $\nu_{23} = (\Delta - \nu_Q)$, respectively, and one double quantum coherence $\rho_{13}(t)$ with precession frequency 2Δ . In this notation, Δ is the offset from resonance. The precession frequencies of the single quantum coherences correspond to the transition frequencies illustrated in Figure 1. Diagonal density matrix elements can be used to construct two linearly independent combinations of eigenstate populations: $(\rho_{11} - \rho_{33}) = \langle \hat{I}_Z \rangle$ is the expectation value of Zeeman polarization, and $(\rho_{11} - 2\rho_{22} + \rho_{33}) = \langle \hat{Q}_Z \rangle$ is the expectation value of quadrupole order. Theoretical expressions for the relaxation behavior of the five independent density matrix elements are easy to calculate in terms of the Redfield

elements R_{ijkl} , which are in turn expressed in terms of spectral densities for molecular motion using the equations

$$R_{ijkl} = \int_0^\infty \exp[i\tau(\omega_{ik} - \omega_{jl})] \langle i | \hat{\mathcal{H}}'(t) | j \rangle \times \langle k | \hat{\mathcal{H}}'(t + \tau) | l \rangle^* d\tau \quad (3)$$

$$\hat{\mathcal{H}}'(t) = \sum_{m=-2}^2 (-1)^m A_{-m}^{(2)} \sum_{k=-2}^2 [D_{mk}^{(2)*}(t) - \langle D_{mk}^{(2)*}(0) \rangle] T_k^{(2)}(\text{PAS}) \quad (4)$$

Here the $A_{-m}^{(2)}$ are second rank spherical tensor spin operators, the $D_{mk}^{(2)}(t)$ are the time-dependent Wigner rotation matrix elements, the $T_k^{(2)}(\text{PAS})$ are spherical components of the quadrupole coupling tensor, expressed in its principal axis system (PAS), and the angular brackets $\langle \rangle$ denote an ensemble average. The $D_{mk}^{(2)}(t)$ depend on Euler angles, $\alpha(t)$, $\beta(t)$, and $\gamma(t)$, which define the time-dependent orientation of the PAS relative to a laboratory-fixed frame. The inclusion of the term $\langle D_{mk}^{(2)*}(0) \rangle$ is necessary to ensure that the relaxation Hamiltonian fluctuates about a mean value of zero, so that the Fourier transform, defined in equation (3), is convergent. In isotropic liquids the $\langle D_{mk}^{(2)*}(0) \rangle$ are zero, but in liquid crystals they define characteristic order parameters of the anisotropic phase.

Without further analysis, several implications of the theory embodied in equations (2)–(4) are apparent. First of all, since $\mathcal{H}'(t)$ gains its time dependence exclusively through orientational variables, deuteron relaxation is sensitive only to rotational motion. This implies that the spatial order characteristic of complex mesophases is not directly probed by deuteron relaxation measurements. Instead, it is necessary to rely on theories which approximate the coupling between translation and rotation. Partially for this reason, most detailed interpretations of deuteron relaxation have been confined to the nematic phase, where translational order is unimportant. Secondly, the appearance of order parameters in the fluctuating Hamiltonian leads ultimately to expressions for measurable relaxation rates which also depend on the orientational order. This implies that the spectral density functions for motion in ordered environments are fundamentally different from those for isotropic liquids. Finally, since the Redfield relaxation matrix elements depend on the average of the product of elements of $\mathcal{H}'(t)$, they include higher-rank order parameters of the form $\langle D_{mk}^{(2)*}(0) D_{mk}^{(2)*}(0) \rangle$. In principle such quantities can be derived from relaxation studies, but they do not influence the equilibrium spectra.

In oriented nematic phases the observed quadrupole splitting is proportional to $\frac{1}{2}(3 \cos^2 \beta_{\text{MP}} - 1)$, where β_{MP} is the angle between the largest component of the electric field gradient (EFG) tensor, q_{zz} , and the molecule fixed Z axis. Typically, in organic molecules, deuteron quadrupole coupling tensors have the largest component coincident with the C–D bond direction. Hence, C–D bonds which make different angles with the molecular Z axis give rise to resolved quadrupolar doublets, whose relaxation behavior can be determined independently. This provides a uniquely powerful way to investigate rotational anisotropy, but requires that the relaxation rates for each

deuteron be expressed in terms of spectral densities for the overall rotation of the molecule-fixed coordinate system. Thus, it is useful to decompose the Euler rotation from laboratory to PAS frames, Ω_{LP} , into separate transformations: a time-dependent transformation from laboratory to molecule-fixed coordinates $[\alpha_{LM}(t), \beta_{LM}(t), \gamma_{LM}(t)]$, followed by a time-independent transformation to the PAS of each individual deuterated site $(\alpha_{MP}, \beta_{MP}, \gamma_{MP})$. It can be shown¹ that there are then just three distinct spectral density functions, given by the equations

$$J_m(m\omega_0) = \frac{1}{(T_0^{(2)})^2} \sum_{k=-2}^2 \sum_{k'=-2}^2 \sum_{n=-2}^2 \sum_{n'=-2}^2 T_n^{(2)} T_{n'}^{(2)*} \quad (5)$$

$$\times D_{kn}^{(2)}(\Omega_{MP}) D_{k'n'}^{(2)*}(\Omega_{MP}) J_{mkk'}(m\omega_0)$$

where $m = 0, 1$, or 2 , and

$$T_0^{(2)} = \frac{\sqrt{6}}{4} \frac{e^2 q_{zz} Q}{\hbar} \quad (6a)$$

$$T_{\pm 1}^{(2)} = 0 \quad (6b)$$

$$T_{\pm 2}^{(2)} = \frac{\eta}{4} \frac{e^2 q_{zz} Q}{\hbar} \quad (6c)$$

Here $\eta = (q_{xx} - q_{yy})/q_{zz}$ is the asymmetry parameter of the deuteron EFG tensor. In most cases, η is small enough to ignore, and this greatly simplifies the evaluation of equation (5). Molecular motion appears in this expression through the Fourier transforms of correlation functions of time-dependent Wigner rotation matrix elements:

$$J_{mkk'}(m\omega_0) = \int_0^\infty \exp(-im\omega_0\tau) C_{mkmk'}(\tau) d\tau \quad (7a)$$

$$C_{mkmk'}(\tau) = \langle E_{mk}^{(2)*}[\Omega_{LM}(t)] E_{mk'}^{(2)}(\Omega_{LM}(t + \tau)) \rangle \quad (7b)$$

$$E_{mk}^{(2)}[\Omega_{LM}(t)] = D_{mk}^{(2)}[\Omega_{LM}(t)] - \langle D_{mk}^{(2)}[\Omega_{LM}(0)] \rangle \quad (7c)$$

In essence, the spectral densities, $J_m(m\omega_0)$ are Fourier transforms of certain correlation functions which relate the orientation of a molecule at time t to the orientation at a later time $t + \tau$. The key idea is that by the appropriate selection of relaxation experiments, the different spectral densities for individual deuterons can be determined as a function of temperature, Larmor frequency ω_0 (magnetic field strength), and orientation with respect to the static field (for sufficiently rigid mesophases). This constitutes the maximum amount of information available from deuteron relaxation experiments.

It is implicit in the formalism presented here that relaxation during rf pulses can be ignored. When this is not the case, for example in spin lock measurements in the rotating frame ($T_{1\rho}$), the same spectral densities arise but some must be evaluated at the rf field amplitude, ω_1 , rather than integer multiples of the Larmor frequency.⁹

3 EXPERIMENTAL DESIGN

Designing experiments to determine spectral densities amounts to choosing a particular state of the density matrix,

calculating its relaxation rate in terms of spectral densities, designing a rf pulse sequence that creates the desired state, and measuring the relaxation time. Pulse sequences that are currently being used to create specific population distributions or coherences are summarized in Table 1. Strategies for using combinations of experiments to determine the individual spectral densities from these measurements will be described in this section. Salient practical aspects will also be discussed: which techniques give the most reliable results and where potential problems in implementation are anticipated. To a certain extent this depends on the details of the spin system, i.e. the number and relative order of magnitude of quadrupolar splittings, and the degree of orientational order of the liquid crystal, S_{zz} and $(S_{xx} - S_{yy})$.

To date, most relaxation experiments have focused on determining $J_1(\omega_0)$ and $J_2(2\omega_0)$ from the recovery of nonequilibrium population distributions. These are the simplest, most reliable and accurate experiments. In principle, $J_1(\omega_0)$ and $J_2(2\omega_0)$ can be obtained from any two relaxation experiments which depend on linearly independent combinations of these two spectral densities. These include nonselective and selective inversion recovery measurements of Zeeman polarization, conventional (JB) and broadband (BBJB) Jeener–Broekaert excitation of quadrupole order, and two-dimensional measurements of the decay rate of double quantum coherence. In practice, the accuracy of selective inversion recovery experiments is limited because the recovery curves are biexponential. The formulae given in Table 1 refer to the initial slope of the recovery, but this is difficult to measure without introducing systematic errors. Nonselective inversion recovery with quadrupolar echo detection (IRQE) does not suffer from this disadvantage, and is the method of choice for measuring T_{1Z} . Because deuteron relaxation times in liquid crystals are short there is no need to resort to inherently less accurate methods such as saturation recovery or progressive saturation.

For studies of thermotropic liquid crystals two potentially serious instrumental problems arise. The first is temperature control: the quadrupole splitting is directly proportional to order parameters which can be strongly temperature dependent. Close to the nematic–isotropic phase transition, where the order parameter changes most rapidly, temperature coefficients as large as 5 kHz K^{-1} have been observed.¹⁰ Temperature drifts, gradients and instabilities as small as a few millidegrees can then lead to severe line broadening. Moreover, in frequency-selective preparation sequences, such as the conventional two-pulse JB sequence, a temperature drift translates into irreproducible changes in the amount of quadrupole order created. In general, accurate measurements of T_{1Z} and T_{1Q} require temperature control and gradients to less than 0.1 K , preferably to within 0.01 K . Secondly, in nematic liquid crystals, quadrupolar splittings approaching 100 kHz are common. In order to achieve uniform inversion over such large spectral widths, rf field strengths of $\nu_1 \approx 150 \text{ kHz}$ are required (typical 90° pulse lengths of $1.5\text{--}2.0 \mu\text{s}$ in a 5 mm coil). Thus, high-power amplifiers similar to those required for solid state ^2H NMR are essential. Fortunately, instrumentation with the necessary capabilities is now commercially available.

It has been shown¹¹ that the best procedure for determining $J_1(\omega_0)$ and $J_2(2\omega_0)$ is not the conventional JB experiment designed to retain both quadrupole and Zeeman order. Rather, two separate IRQE and BBJB experiments are performed which can be optimized independently for maximum

Table 1 Relaxation Experiments and Measured Spectral Densities

	Spectral Density ^a
<i>Populations</i>	
Nonselective T_{1Z} (IRQE)	
180- T^b -90 _x - τ -90 _y	$2J_1(\omega_0) + 8J_2(2\omega_0)$
Broadband T_{1Q} (BBJB)

Conventional Jeener-Broekaert (JB)	
90 _x - τ -45 _y - T -45 _y	Sum: $2J_1(\omega_0) + 8J_2(2\omega_0)$ Difference: $6J_1(\omega_0)$
Selective T_{1Z}^c	
180 _x ^A - T -90 ^A	$5J_1(\omega_0) + 2J_2(2\omega_0)$
<i>Coherences</i>	
Quadrupolar echo T_{2e}	
90 _x - T -90 _y	$3J_0(0) + 3J_1(\omega_0) + 2J_2(2\omega_0)$
Multipulse quadrupolar echo T_2 (MQE)	
90 _x - τ -(90 _y -2 τ)- _n	Short τ : $3J_0(0) + 5J_1(\omega_0) + 2J_2(2\omega_0)$ Long τ : $3J_0(0) + 3J_1(\omega_0) + 2J_2(2\omega_0)$
($T = 2n\tau$)	
Selective single quantum T_2^c	
90 _x ^A - $T/2$ -180 ^A - $T/2$ -	$3J_0(0) + 3J_1(\omega_0) + 2J_2(2\omega_0)$
Double quantum T_{DQ}	
90 _x - τ -90 _x - $T/2$ -180- $T/2$ -90	$2J_1(\omega_0) + 4J_2(2\omega_0)$

^aUnits of $(3\pi^2/4)(e^2q_{zz}Q/\hbar)^2$.^b T denotes the relaxation delay.^cThe superscript A indicates that the pulse is applied selectively at the frequency of peak A.

precision and accuracy. In particular, the use of broadband (frequency-independent) procedures for exciting quadrupole order, combined with echo detection to avoid pulse recovery problems, was shown to increase greatly the accuracy with which T_{1Q} can be determined.¹¹ This is important because small uncertainties in measured values of the relaxation times propagate into larger errors in determining $J_2(2\omega_0)$.

Figure 2 illustrates the difference between conventional (JB) and broadband (BBJB) excitation of quadrupole order. The sample is pure 4-*n*-pentyl-4'-cyanobiphenyl selectively deuterated (5CB-*d*₆) in the 1,4- and 5-positions of the alkyl chain. Figure 2(a) shows the pulse sequence, spectrum, and quadrupolar order excitation profile for the conventional JB pulse pair, 90_x- τ -45_y. This sequence is inherently frequency selective, with efficiency proportional to $\sin \nu_Q \tau$. The excitation delay of $\tau = 46 \mu\text{s}$ is a particularly unfortunate choice: the spectrum shows that the sign of the quadrupole order is opposite for the C-1 and C-2 methylene deuterons and there is little excitation of quadrupole order for the methyl deuterons (C-5). It is impossible to achieve full excitation of quadrupole order for all the transitions with any single τ value. The BBJB sequence does not suffer from this limitation. Figure 2(b) shows that uniform excitation is achieved by this sequence, with total excitation time $5\tau = 46 \mu\text{s}$. Thus, for materials with several different quadrupole splittings, broadband procedures for exciting quadrupole order are definitely preferable to the simple JB pulse pair. In practice, the choice of τ in the BBJB sequence is not very critical. It is usually sufficient to use a small enough value to excite full quadrupole order for the largest splitting, and this ensures that all others will be uniformly excited. However, it must be noted that all methods of exciting quadrupole order fail as the quadrupole splitting tends to zero. For splittings less than a few kilohertz, the BBJB sequence

described here is somewhat less efficient than the simple two-pulse (JB) excitation sequence. This is demonstrated by the excitation profiles shown for the JB and BBJB sequences in the lower traces of Figures 2(a) and 2(b), respectively. Computer-optimized broadband sequences have now been developed to deal with this problem.¹² In summary, the BBJB experiment has many advantages and is rapidly superseding the conventional JB experiment as the method of choice for measuring T_{1Q} . Moreover, since this technique can be applied successfully to powder patterns (which have a continuous distribution of quadrupolar splittings), it will be useful for measuring the orientation dependence of T_{1Q} in smectic and lyotropic mesophases.

To demonstrate procedures for determining individual spectral densities measurements of relaxation times of a liquid crystal mixture, consisting of 25 mol% of perdeuterated 4-methyl-4'-cyanobiphenyl (1CB-*d*₁₁) and 75 mol% 5CB-*d*₆, will be outlined as a case study.¹³ 5CB-*d*₆ is selectively deuterated on the alkyl chain carbon at positions C-1, C-4 and C-5, as shown in the molecular structure. Figure 3 illustrates the measurement of T_{1Z} using a nonselective inversion pulse followed by quadrupole echo detection. The bottom trace is an equilibrium spectrum, and spectral assignments for each of the quadrupolar doublets are indicated. Dipolar fine structure is apparent on the 1CB transitions, but it can be shown that this does not interfere with the T_{1Z} measurements.

The top trace in Figure 3 shows a partially relaxed spectrum with relaxation delay $T = 1 \text{ ms}$, and all the transitions are inverted. After 10 ms the aromatic doublet of 1CB (peak 5) has recovered substantially while the other lines remain inverted. After 45 ms, the 1CB methyl lines (peak 2) are nulled while the methyl (C-5) deuterons of 5CB (peak 4), which have the longest T_{1Z} , are still inverted. In order to obtain accurate T_{1Z} values from these data, it is necessary to choose a set

Figure 2 Pulse sequences, 5CB- d_6 spectra, and quadrupolar order excitation profiles for (a) the conventional JB pulse pair and (b) the BBJB sequence. For (a) the pulse delay was $\tau = 46 \mu\text{s}$, and in (b) the total excitation time $5\tau = 46 \mu\text{s}$. The simulated quadrupolar order excitation profiles include the effects of finite pulse lengths (90° pulse width of $1.6 \mu\text{s}$). The spectra were recorded at 46.06 MHz

Figure 3 Molecular structures of the binary mixture of 1CB- d_{11} (25 mol%) and 5CB- d_6 . Partially relaxed spectra at 46.06 MHz from the inversion–recovery experiment with quadrupolar echo detection (IRQE) were taken in the nematic phase at 28.2°C . Relaxation delay times are indicated on the left of each trace. Spectral assignments for the labeled peaks in the equilibrium spectrum, shown in the bottom trace, are: (1) deuterons on the first methylene carbon on the alkyl chain of 5CB; (2) methyl deuterons of 1CB; (3) deuterons on the fourth alkyl chain carbon of 5CB; (4) methyl deuterons of 5CB; and (5) aromatic ring deuterons of 1CB

of relaxation delays which span at least one full decade of recovery for every line. T_{1Z} for each deuteron is then obtained by fitting to the equation

$$M(\infty) - M(T) = [M(\infty) - M(0)] \exp(-T/T_{1Z}) \quad (8)$$

Here $M(T)$ is the sum intensity of the quadrupolar doublet at time T , $M(\infty)$ is its thermal equilibrium value, and $M(0)$ is the intensity immediately after inversion. In principle, perfect inversion should give $M(0) = -M(\infty)$. However, erroneous T_{1Z} values are obtained if this is assumed and the data are fitted to a two-parameter equation. A nonlinear fit in which $M(0)$, $M(\infty)$, and T_{1Z} are simultaneously adjusted is more reliable. Typically, 10 or more T values are needed for accurate results.

In the 1CB/5CB mixture, at 28.2°C , T_{1Z} ranges from 9.8 ms for the 1CB aromatic deuterons to 209 ms for the 5CB methyl deuterons. Thus, it is not possible to construct one set of relaxation delays which is appropriate for every transition. Instead, the list must be expanded to include T values which are appropriate for all the relaxation times. In practice, this requires a few preliminary experiments to establish the approximate range of T_{1Z} values, and when the range is large, as many as 20–30 delays may be required. A common source of error in this type of experiment is failure

Figure 4 Partially relaxed spectra at 46.06 MHz from a BBJB experiment on the nematic phase of the binary mixture of 1CB-*d*₁₁ (25 mol%) and 5CB-*d*₆ at 28.2°C. Relaxation delay times are indicated on the left of each trace. Spectral assignments are identical to those given in Figure 3

to wait for full equilibrium between successive scans: it is essential to wait at least five times the longest T_{1Z} value if systematic errors are to be avoided. Thus for the 1CB/5CB mixture, where 2048 scans were accumulated for each of 20 T values, the recycle delay was 1 s and the total experiment time was approximately 12 h.

Next, the BBJB sequence is used to excite quadrupole order uniformly. The relaxation time T_{1Q} can be measured by monitoring the decay of the difference magnetization for each doublet. Typical partially relaxed spectra for the 1CB/5CB binary mixture are shown in Figure 4. Since the difference magnetization for each doublet decays rigorously toward zero, the exponential decay function can be fitted with just two adjustable parameters (the initial intensity and T_{1Q}). Construction of an appropriate list of relaxation delays is as important as for T_{1Z} measurements, and the total experimental time is usually comparable.

Spectral densities may be calculated from the relationships

$$J_1(\omega_0) = \frac{2R_{1Q}}{9\pi^2(e^2q_{zz}Q/h)^2} \quad (9)$$

and

$$J_2(2\omega_0) = \frac{1}{18\pi^2(e^2q_{zz}Q/h)^2}(3R_{1Z} - R_{1Q}) \quad (10)$$

Here $e^2q_{zz}Q/h$ is the quadrupole coupling constant in hertz. When proper precautions are taken, and the signal-to-noise ratio is favorable, it is possible to determine the relaxation rates, $R_{1Z} = 1/T_{1Z}$ and $R_{1Q} = 1/T_{1Q}$, with a precision of 2–5%. This is sufficiently accurate that the use of approximate values for the quadrupole coupling constant should be avoided. Estimated values, from data reported for more or less similar materials, can lead to significant uncertainty in the spectral densities. Wherever possible, low-temperature quadrupole echo lineshapes should be analyzed to determine static values of the relevant quadrupole coupling constants.

While numerous measurements of $J_1(\omega_0)$ and $J_2(2\omega_0)$ have been reported, determinations of $J_0(0)$ are relatively

scarce. Potential dynamic information inherent in this spectral density is very important in the study of liquid crystals. In particular, the spectral density at zero frequency should be exquisitely sensitive to long-wavelength modes of order director fluctuations. Even though this small-angle process contributes in first order only to $J_1(\omega_0)$, higher order calculations¹⁴ reveal contributions to $J_0(\omega)$ which can be large as ω tends to zero.

All methods for determining $J_0(0)$ rely on measuring the dephasing rate of one quantum coherence, and subtracting contributions from $J_1(\omega_0)$ and $J_2(2\omega_0)$. For example, making use of the spectral densities listed in Table 1, it can be shown that $J_0(0)$ is given by

$$J_0(0) = \frac{1}{9\pi^2(e^2q_{zz}Q/h)^2}(4R_2^0 - 2R_{1Z} - 3R_{1Q}) \quad (11)$$

where R_2^0 is the limiting decay rate obtained in a multi-pulse quadrupole echo sequence in the limit of zero pulse spacing ($2\tau \rightarrow 0$), much smaller than $(e^2q_{zz}Q/h)^{-1}$.¹⁵ Alternatively, if the transverse relaxation rate $R_2(\text{sel})$ of one line of the quadrupolar doublet is measured using a selective Carr–Purcell sequence, $J_0(0)$ is given by

$$J_0(0) = \frac{1}{27\pi^2(e^2q_{zz}Q/h)^2}[12R_2(\text{sel}) - 3R_{1Z} - 5R_{1Q}] \quad (12)$$

To date, there is no single method that is successful for measuring T_2 in all liquid crystalline systems. Figure 5 illustrates an efficient 2D procedure appropriate for spectra with many lines. The sample is perdeuterated fluorene dissolved in the nematic phase of 5CB. In this experiment a train of n equally spaced 90_y° refocusing pulses are applied during the evolution period and the acquisition is started at the top of the last echo. The evolution time must therefore be incremented in integral multiples of the echo spacing. For the 2D spectrum shown in Figure 5, the spacing was $2\tau = 300 \mu\text{s}$, and every fifth echo was recorded ($n = 1, 6, 11, \dots, 76$). Thus the spectral width in the f_1 frequency domain is $\pm 1/(20\tau) = \pm 333 \text{ Hz}$. The ordinary spectrum is recovered as a slice along $f_1 = 0$, and is displayed at the right edge of the contour plot (spectral assignments are indicated). Each peak has a Lorentzian profile in f_1 , and its T_2 can be determined simply from the linewidth at half maximum. However, before relying on these T_2 values to determine $J_0(0)$ it is necessary to consider the pulse spacing dependence of the relaxation time,¹⁵ and potential sources of systematic errors. In some cases, T_2 may be so short that only a few echoes can be observed, and the digital resolution in f_1 is then insufficient for accurate linewidth measurements. It is encouraging that the T_2 values determined in the frequency domain, from the 2D linewidths, are found to agree (within experimental error) with those determined in the time domain by fitting the line intensities as a function of relaxation delay.

Unresolved dipolar interactions are a potentially serious source of error in multiple pulse quadrupolar echo measurements of T_2 in liquid crystals. Dipolar precession is not refocused by the nonselective 90_y° pulses, and unresolved dipolar couplings produce apparent dephasing which can be confused with a true T_2 process. This problem is also unavoidable in nonselective two-pulse procedures where the echo amplitude

Figure 5 A 2D method for determining T_2 s in a multiline spectrum. The sample is perdeuterated fluorene- d_{10} in the nematic phase of 5CB. The normal ^2H NMR spectra (46.06 MHz) is obtained from the $f_1 = 0$ slice through the data matrix, and is shown to the right of the contour plot. T_2 of each line is obtained from the full width at half maximum of the Lorentzian lineshape for the corresponding slice in f_2 , as shown on the left. The pulse sequence for this experiment is shown, and for this data set the pulse spacing was $2\tau = 300 \mu\text{s}$, and every fifth echo was recorded

is monitored as a function of pulse spacing to give T_{2e} . The use of selective pulses, designed to monitor spin echoes from one-half of the quadrupolar doublet, circumvents this difficulty. However, in samples with small quadrupolar splittings and many lines it may not be possible to achieve adequately selective pulses. Alternatively, all precession of the transverse magnetization can be suppressed by using the multiple quadrupolar echo experiment with closely spaced 90_y pulses. This achieves effective spin locking when the pulse spacing is smaller than the inverse of the largest quadrupole splitting. In practice, this procedure requires a very robust temperature controller to avoid overheating the sample. A general, accurate method of measuring $J_0(0)$ in liquid crystals remains to be established, and this continues to be a topic of current research.

The decay rate of double quantum coherence for a single deuteron depends exclusively on $J_1(\omega_0)$ and $J_2(2\omega_0)$. Thus there is no additional information to be gained by measuring this relaxation rate that cannot be obtained more accurately from simple measurements of T_{1Z} and T_{1Q} . In a few carefully chosen systems, with well-resolved deuteron dipolar coupling, it has been possible to create and monitor the decay of

both double- (R_{1313}) and four-quantum (R_{1414}) coherences.¹⁶ This permitted determination of the cross-correlation terms in the motion of two different quadrupole coupling tensors, and provided insight into rotational anisotropy of small rigid solutes in liquid crystalline solvents. Unfortunately, this method cannot be readily extended to typical liquid crystal molecules because of extensive dipolar couplings, which are usually too small to be resolved and thus contribute to the apparent multiple-quantum linewidth.

4 SITE SPECIFIC SPECTRAL DENSITIES

Deuteron relaxation in liquid crystals gains much of its utility from the unambiguous way in which the spectral densities depend on the orientation of the EFG tensor with respect to molecule-fixed coordinates. By measuring spectral densities for deuterons with several different orientations, it is possible to obtain a very stringent test of models of rotational motion. The general orientation dependence, expressed in

equation (5), can be quite complex, and it is useful to consider the special case of a linear molecule. In this case, the EFG tensor has zero asymmetry parameter, and the largest component is collinear with the molecule-fixed Z axis ($\beta_{MP} = 0$). The fourfold summation in equation (5) then collapses to a single term:

$$J_m(m\omega_0) = J_{m00}(m\omega_0) \quad (13)$$

It can be shown that the spectral densities $J_{m00}(m\omega_0)$ are determined exclusively by processes which reorient the long molecular axis. These include order director fluctuations, which make a large contribution only to $J_{100}(\omega_0)$, and molecular reorientation which contributes to both $J_{100}(\omega_0)$ and $J_{200}(2\omega_0)$. Illustrative data for cyanoacetylene-*d* dissolved in a commercial nematic liquid crystal mixture (Merck Phase V)¹⁷ are shown in Figure 6. $J_1(\omega_0)$ clearly includes a frequency-dependent contribution which is absent from $J_2(2\omega_0)$. Numerous investigations of the deuteron relaxation of small rigid solutes in nematic phases have made use of this frequency dispersion to isolate the contributions from director fluctuations.

Measurements¹⁸ have demonstrated that director fluctuations do not play a major role in the deuteron relaxation of the liquid crystal molecules themselves. The rotational motion of typical nematogens is apparently slow enough to occur on approximately the same timescale as director fluctuations. It can then be shown that cross-correlation effects act to quench the contribution of director fluctuations, so that the spectral densities can be interpreted exclusively in terms of single-molecule rotation.¹⁹

Figure 6 Spectral densities $J_1(\omega_0)$ (open symbols) and $J_2(2\omega_0)$ (solid symbols) for cyanoacetylene-*d* in nematic Merck Phase V.¹⁷ Data were acquired at several Larmor frequencies: triangles, $\nu_0 = 4.6$ MHz; circles, $\nu_0 = 9.2$ MHz; squares, $\nu_0 = 38.4$ MHz. The experimental points are joined by lines to guide the eye. For reasons discussed in the text, $J_1(\omega_0)$ depends on the Larmor frequency while $J_2(2\omega_0)$ does not

Figure 7 Models used to describe molecular motion in oriented environments. (a) rotational diffusion (RD), (b) anisotropic viscosity (AV) and (c) the ‘third rate’ (TR) model

While a full discussion of molecular motion is beyond the scope of this article, three popular rotational models are illustrated in Figure 7: rotational diffusion (RD),²⁰ anisotropic viscosity (AV),²¹ and the ‘third rate’ (TR) model.²²

Small-step rotational diffusion of a symmetric rotor is fully characterized by two correlation times, $\tau_{\perp} = 1/(6D_{\perp})$ and $\tau_{\parallel} = 1/(6D_{\parallel})$, where $D_{\perp}$ and $D_{\parallel}$ are rotational diffusion constants. If the diffusion tensor is assumed to be diagonal in laboratory-fixed coordinates, where its principal components are related to anisotropic viscosity coefficients, the relevant correlation times for this ‘anisotropic viscosity’ model are still labeled $\tau_{\perp}$ and $\tau_{\parallel}$ but their physical meaning is different. Assuming that the nematic director remains parallel to the magnetic field, τ_{β} and τ_{α} in the TR model have the same physical significance as $\tau_{\perp}$ and $\tau_{\parallel}$ (respectively) in the AV model. The third rate is characterized by a correlation time τ_{γ} for rotation about the long molecular axis, which can occur in steps of arbitrary size as specified by a collision parameter p , where $0 \leq p \leq 1$.

The nematogen 2-fluorenyl 4'-tetradecyloxybenzoate-*d*₉ (FLOC₁₄-*d*₉) provides an excellent example of how spectral densities can be used to test these rotational models. Figure 8 shows the molecular structures and the assigned NMR spectrum in the nematic phase of a binary mixture of FLOC₁₄-*d*₉ and *p*-xylene-*d*₁₀ (~10 mol%). The temperature dependence of the spectra gives the orientational order parameters of both molecules.²³ By measuring and analyzing T_{1Z} and T_{1Q} for all

Figure 8 Quadrupole echo spectrum at 32.8 MHz with spectral assignments for a binary mixture of FLOC₁₄-d₉ and *p*-xylene-d₁₀ in the nematic phase. Analysis of relaxation data for this sample using the TR model provided correlation times for both the rigid solute and the flexible liquid crystal molecule²⁴

the lines as a function of temperature, it was possible to determine rotational correlation times for both components of the mixture.²⁴

Measurements on pure FLOC₁₄-d₉, which has deuterons at five different orientations of the EFG tensor, yielded 10 independent spectral densities at each temperature.¹⁸ A representative selection of the extensive data is shown in Figure 9 which gives the spectral densities for two molecular sites—the 3 ($\beta_{MP} = 54.65^\circ$) and 5,8 ($\beta_{MP} = 78.15^\circ$) positions. The points are experimental spectral densities, and the lines represent a nonlinear least-squares fit of the data from all positions to the TR model.

The problem of fitting the spectral densities to the various motional models is highly overdetermined, and the quality of the fit can be used to assess the validity of each model. Not surprisingly, it was found that no two-parameter model was capable of simultaneously fitting the spectral density data for all the sites. The TR model, with four independently adjustable parameters, provided by far the best fit. Figure 10(a) shows a 3D minimum $\Delta\chi^2$ surface (68% confidence boundaries) in the correlation time phase space (τ_α , τ_β , τ_γ), for FLOC₁₄-d₉ at 135.7°C.¹⁸ At this temperature the order parameter $S_{zz} = 0.523$, and the correlation times are $\tau_\alpha = 610 \pm 300$ ps, $\tau_\beta = 1050 \pm 250$ ps, and $\tau_\gamma = 266 \pm 20$ ps. Measuring the temperature dependence of the correlation times allowed

Figure 9 Individual spectral densities, $J_1(\omega_0)$ and $J_2(2\omega_0)$, for positions 3 and 5,8 of FLOC₁₄-d₉, as a function of inverse temperature. Closed circles are $J_1(\omega_0)$ measured at 46 MHz, closed triangles are $J_1(\omega_0)$ at 38.4 MHz, closed squares are $J_2(2\omega_0)$ at 46 MHz and closed diamonds are $J_2(2\omega_0)$ at 38.4 MHz. The open symbols, which are connected by dotted lines to guide the eye, are fits of the 46 MHz data, from all positions, to the third rate model of molecular reorientation. (Adapted from Goetz et al.¹⁸)

activation energies for the three independent rotations to be determined.

5 SAMPLE ROTATION EXPERIMENTS

When a liquid crystal sample is rotated in a magnetic field, the diamagnetic susceptibility anisotropy results in a torque on the director which tends to align it either parallel or perpendicular to the field. In nematic mesophases, the opposing viscous forces are too weak, and spontaneous realignment of the director occurs. This is unfortunate, because when the director can be rotated, profound changes are observed in both the NMR spectrum and relaxation times. Deuteron spectra with well-resolved doublets are observed only when the director is aligned with respect to the field. If it is not so aligned, the distribution of molecular orientations about the director

Figure 10 TR model parameters for pure FLOC_{14-d9} in the nematic phase at 135.7°C. (a) Constant $\Delta\chi^2$ boundary of 68% confidence in the 3D parameter space of the TR model, $(\tau_\alpha, \tau_\beta, \tau_\gamma)$. (b) Arrhenius plots of the temperature dependence of the motional correlation times; τ_α data are shown as squares, τ_β as circles, and τ_γ as triangles. The error bars correspond to the 68% confidence boundaries, and the lines are least squares fits of the data which give the activation energies. (Adapted from Goetz et al.¹⁸)

produces a distribution of doublet splittings, and the resulting characteristic spectra are reminiscent of the powder patterns observed in solid state ^2H NMR. Analysis of these lineshapes and rotation patterns can provide a wealth of information about the orientational distribution function. This technique has been especially successful in elucidating structure and organization in a magneto-aligned chiral smectic C phase, S_C^* .²⁵

Relaxation measurements as a function of sample orientation are relatively scarce, in part because methods for obtaining individual spectral densities from complex powder patterns have only been devised in the 1990s.²⁶ The information available from such experiments can be appreciated by considering the simple case of a uniaxial phase, such as smectic A or hexatic smectic B. It can then be shown²⁷ that the spectral densities are given by

$$J_0(\beta, 0) = \frac{1}{4}(1 - 3\cos^2\beta)^2 J_0(0) + 3\cos^2\beta \times \sin^2\beta J_1(0) + \frac{3}{4}(1 - \cos^2\beta)^2 J_2(0) \quad (14a)$$

$$J_1(\beta, \omega_0) = \frac{3}{2}\cos^2\beta \sin^2\beta J_0(\omega_0) + \frac{1}{2}(1 - 3\cos^2\beta + \cos^4\beta)J_1(\omega_0) + \frac{1}{2}(1 - \cos^4\beta)J_2(\omega_0) \quad (14b)$$

$$J_2(\beta, 2\omega_0) = \frac{3}{8}(1 - \cos^2\beta)^2 J_0(2\omega_0) + \frac{1}{2}(1 - \cos^4\beta) \times J_1(2\omega_0) + \frac{1}{8}(1 + 6\cos^2\beta + \cos^4\beta)J_2(2\omega_0) \quad (14c)$$

If T_{1Z} and T_{1Q} are analyzed to yield $J_1(\beta, \omega_0)$ and $J_2(\beta, 2\omega_0)$ as functions of sample rotation angle β , inversion of equations (14b) and (14c) will yield six spectral densities: $J_0(\omega_0)$, $J_1(\omega_0)$, $J_2(\omega_0)$, $J_0(2\omega_0)$, $J_1(2\omega_0)$, and $J_2(2\omega_0)$. It must be noted that these results are applicable only for uniaxial phases, and most phases which are rigid enough to support sample rotation have more complicated, biaxial symmetry. While this further complicates the orientation dependence of the spectral densities, it should not preclude using them to test motional models.

6 CONCLUSIONS

This article has discussed and summarized the existing experimental methods which are used to measure various deuteron relaxation times in liquid crystals. Accurate determination of appropriate combinations of relaxation rates allows the derivation of the individual spectral density functions $J_1(\omega_0)$, $J_2(2\omega_0)$, and, occasionally, $J_0(0)$. These spectral densities are Fourier transforms of rotational correlation functions and can be interpreted in terms of models of molecular motion. Currently, when appropriate precautions are taken, it is possible to measure spectral densities with an accuracy of 2–5%. This places very tight constraints on acceptable theoretical descriptions of molecular dynamics. In the nematic phase of thermotropic liquid crystals, performing these experiments as a function of temperature and magnetic field strength (ω_0) provides a rigorous test for models of molecular motion in the presence of an orientating potential. Extension of the measurements to more complex ordered smectic, lyotropic, and discotic mesophases offers the possibility of determining the orientation dependence of the relaxation rates, and represents a dramatic increase in the available information.

In conclusion, measuring ^2H NMR relaxation rates is a powerful and important method for investigating and understanding molecular dynamics in liquid crystal samples.

1 INTRODUCTION

The effect of dynamic processes on high-resolution NMR spectra in liquids was first observed¹ in 1953 soon after the discovery of the chemical shift² and spin–spin coupling phenomena.^{1,3} Since then the effect has been extensively used to study a wide range of dynamic processes in liquids including protolysis, solvation, hindered rotation, bond shift tautomerism, and a variety of other isomerization reactions.^{4,5} The effect of dynamic processes on the high-resolution spectra is manifested in line broadening, coalescence, and eventual line narrowing, yielding motionally averaged spectra with average magnetic parameters. The effect on the lineshape is most pronounced when the exchange rate is of the order of the magnetic interactions. For protons these range from several hertz to several kilohertz, while for ¹³C the range is an order of magnitude larger. Quantitative studies can generally be made within the range where the lifetime broadening or the exchange-narrowed linewidth exceeds that of the natural width, i.e. $1\text{--}10^6\text{ s}^{-1}$ for protons and one to two orders of magnitude faster for carbon-13.

Proton or carbon-13 high-resolution spectra of molecules dissolved in liquid crystalline solvents usually exhibit more complicated structures than in normal (isotropic) liquids and often span a wider frequency range.⁶ This is so because in anisotropic solvents, in addition to the scalar spin–spin coupling and isotropic chemical shift, anisotropic interactions also affect the spectrum. These include intramolecular dipole–dipole interactions, anisotropic indirect spin–spin couplings, anisotropic chemical shifts, and, for $I > \frac{1}{2}$ nuclei, also quadrupolar interactions. The fast anisotropic motion of the molecules reduces these interactions, but unlike in isotropic liquids their averages are, in general, not zero and depend on the ordering characteristics of the molecules in the liquid crystals. If the number of magnetic nuclei in the molecule is not too large (say below 10) a well-resolved high-resolution spectrum

can usually be observed, but for more nuclei the number of lines becomes exceedingly large and the spectrum unresolved. It should be emphasized that the fast translational diffusion completely averages out the intermolecular dipolar interactions. Otherwise a featureless spectrum as in solids would always be observed.

When the solute molecules dissolved in liquid crystals undergo dynamic processes, lineshape changes similar to those observed in isotropic liquids take place.⁷ We refer to this phenomenon as ‘dynamic NMR in liquid crystalline solvents’ and in the present article we outline its basic theory and review some applications. Because of the more complex structure of the spectra in liquid crystalline solutions the interpretation is more complicated, but the basic principles are the same as in isotropic liquids. On the other hand, due to the larger interactions involved, the dynamic range over which kinetic parameters can be measured is much wider. Nuclei with spins $I > \frac{1}{2}$ usually exhibit splittings due to quadrupole interactions which are often much larger than the dipolar or chemical shift interactions. The structure of the spectrum is then predominantly determined by the quadrupole splittings with the other interactions often within the experimental linewidth.

We start the review by extending the theory of dynamic lineshape in isotropic liquids to the liquid crystalline case by adding anisotropic terms to the spin Hamiltonian (Section 2). After a short section (3) dealing with some experimental aspects, we review applications (Section 4) for spin $I = \frac{1}{2}$ nuclei (¹H and ¹³C), including the use of multiple quantum spectroscopy (Section 5). In Sections 6 and 7 we discuss applications of one- and two-dimensional dynamic NMR to deuterium and in Section 8 we briefly describe a dynamic deuterium study using quadrupole echo pulse trains.

2 DYNAMIC NMR LINESHAPES IN LIQUID CRYSTALLINE SOLUTIONS

The theory of dynamic NMR lineshapes in anisotropic liquids is, in principle, identical to that for isotropic liquids.^{1,5,8–12} However, since dipolar interactions involve essentially all magnetic nuclei in the molecule, and for homonuclei cases these interactions are usually larger than the chemical shifts, the NMR spectra always correspond to combination transitions. The simple Bloch–McConnell type treatment⁸ is therefore not adequate for the analysis of the dynamic lineshapes and the more general density matrix formalism must be used.^{9–13} We shall restrict ourselves to intramolecular rearrangement kinetics because higher order processes involving two or more molecules¹⁰ have not been applied so far in liquid crystalline solutions. The equation of motion of the density matrix, $\hat{\rho}(t)$, during free induction decay, is then:

$$\begin{aligned} \frac{d\hat{\rho}(t)}{dt} = & -i[\hat{\mathcal{H}}, \hat{\rho}(t)] + k[\hat{R}\hat{\rho}(t)\hat{R}^{-1} - \hat{\rho}(t)] - \hat{\rho}_{\text{od}}(t)/T_2 \\ & - [\hat{\rho}_0 - \hat{\rho}_{\text{dg}}(t)]/T_1 \end{aligned} \quad (1)$$

where $\hat{R}$ is an operator describing the exchange process, k the rate constant for the reaction, $\hat{\rho}_0$ the equilibrium density

matrix, and $\hat{\rho}_{\text{dg}}(t)$ and $\hat{\rho}_{\text{od}}(t)$ the diagonal and off-diagonal parts of $\hat{\rho}(t)$ which are assumed to relax by respectively single longitudinal and transverse modes. Limiting ourselves to the homonuclei case the Hamiltonian, $\hat{\mathcal{H}}$, in the rotating coordinate system includes both single and binuclear terms,

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_Q + \hat{\mathcal{H}}_S \quad (2)$$

where

$$\hat{\mathcal{H}}_Z = - \sum_i \omega_0(1 - \sigma_i) \hat{I}_{iz} = \sum_i \omega_i \hat{I}_{iz} \quad (3a)$$

$$\hat{\mathcal{H}}_Q = \sum_i \omega_{Qi} [(\hat{I}_{iz})^2 - \hat{I}_i(\hat{I}_i + 1)/3] \quad (3b)$$

$$\begin{aligned} \hat{\mathcal{H}}_S = \sum_{i < j} \{ & 2(D_{ij} + J_{ij}^a) [\hat{I}_{iz} \hat{I}_{jz} - (\hat{I}_{i+} \hat{I}_{j-} + \hat{I}_{i-} \hat{I}_{j+})/4] \\ & + J_{ij} [\hat{I}_{iz} \hat{I}_{jz} - (\hat{I}_{i+} \hat{I}_{j-} + \hat{I}_{i-} \hat{I}_{j+})/2] \} \end{aligned} \quad (3c)$$

In these equations ω_0 and ω_i are the reference and resonance frequencies in the rotating frame, σ_i the motionally averaged chemical shift, ω_{Qi} the average quadrupole interaction, D_{ij} the average direct dipole-dipole interaction, and J_{ij}^a and J_{ij} are respectively the average anisotropic and scalar spin-spin couplings. The sum is over all magnetic nuclei in the molecule assumed to belong to the same isotope (homonuclei). The averaged anisotropic parameters, $T = \sigma_i$, ω_{Qi} , D_{ij} , J_{ij}^a , are related to their static tensorial components, $T_{\alpha\beta}$, in the molecular-fixed frame $\alpha, \beta = x, y, z$ via the so-called motional constants, C_α^2 .^{14,15} The liquid crystal is assumed to have a nonpolar cylindrical symmetry defined by a director which aligns parallel to the magnetic field. The molecular orientation distribution function can then be expanded in even orders of the (real) spherical harmonic functions

$$\begin{aligned} P(\theta, \phi) = \frac{1}{4\pi} + C_{3z^2-r^2}^2 D_{3z^2-r^2}^2 + C_{x^2-y^2}^2 D_{x^2-y^2}^2 \\ + C_{xz}^2 D_{xz}^2 + C_{yz}^2 D_{yz}^2 + C_{xy}^2 D_{xy}^2 + O(D^4) \end{aligned} \quad (4)$$

where the D_α^2 s are normalized so that $\int_0^{2\pi} \int_0^\pi D_\alpha^2 D_{\alpha'}^2 \sin \theta \, d\theta \, d\phi = (1/4\pi) \delta_{\alpha\alpha'}$

$$\left. \begin{aligned} D_{3z^2-r^2}^2 &= \left(\frac{\sqrt{5}}{4\pi} \right) \frac{1}{2} (3 \cos^2 \theta - 1) \\ D_{x^2-y^2}^2 &= \left(\frac{\sqrt{15}}{4\pi} \right) \frac{1}{2} (\sin^2 \theta \cos 2\phi) \\ D_{xy}^2 &= \left(\frac{\sqrt{15}}{4\pi} \right) \frac{1}{2} (\sin^2 \theta \sin 2\phi) \\ D_{xz}^2 &= \left(\frac{\sqrt{15}}{4\pi} \right) (\sin \theta \cos \theta \cos \phi) \\ D_{yz}^2 &= \left(\frac{\sqrt{15}}{4\pi} \right) (\sin \theta \cos \theta \sin \phi) \end{aligned} \right\} \quad (5)$$

and $C_\alpha^2 = 4\pi \int_0^{2\pi} \int_0^\pi P(\theta, \phi) D_\alpha^2 \sin \theta \, d\theta \, d\phi$. The averages of the anisotropic interactions are given by

$$\begin{aligned} T = \frac{1}{\sqrt{15}} \left\{ C_{3z^2-r^2}^2 \frac{2}{\sqrt{3}} [T_{zz} - \frac{1}{2}(T_{xx} + T_{yy})] \right. \\ + C_{x^2-y^2}^2 (T_{xx} - T_{yy}) + C_{xz}^2 (T_{xz} + T_{zx}) \\ \left. + C_{yz}^2 (T_{yz} + T_{zy}) + C_{xy}^2 (T_{xy} + T_{yx}) \right\} \end{aligned} \quad (6)$$

Molecular symmetry will reduce the number of nonzero motional constants by choosing the appropriate molecular coordinates x, y , and z .¹⁵

To calculate the time domain signal it is necessary to compute the expectation value of the transverse magnetization

$$M_+(t) = \text{Tr}(\hat{\rho}(t) \hat{I}_+) = \sum_{k,\ell} \rho_{k\ell}(t) (I_+)_{\ell k} \quad (7)$$

which upon Fourier transformation yields the frequency spectrum

$$I(\omega) = \text{Re} \int M_+(t) \exp(-i\omega t) \, dt \quad (8)$$

As $(I_+)_{\ell k} \propto \delta_{k,l-1}$ we only need off-diagonal elements of the density matrix of the type $\rho_{k,k+1}(t)$. Consequently, since the Hamiltonian is secular and the exchange operators only mix states of the same total azimuthal quantum number, m_l we extract from equation (1) those blocks of equations which couple between m_k and m_{k-1} states. For a spin system with N nuclei of spin $I = \frac{1}{2}$, there are N such blocks with dimensions

$$\begin{aligned} (N!)^2 / [(N/2 - m)!(N/2 + m)!(N/2 + 1 - m) \\ \cdot (N/2 - 1 + m)!] \end{aligned} \quad (9)$$

The largest blocks are the $0 \rightarrow \pm 1$ transitions for N even and the $-\frac{1}{2} \rightarrow +\frac{1}{2}$ transitions for N odd with dimensions

$$\frac{N}{N+2} \frac{(N!)^2}{[(N/2)!]^4} \quad \text{and} \quad \left(\frac{(N+1)}{2} \right)^2 \frac{(N!)^2}{[((N+1)/2)!]^4} \quad (10)$$

respectively. The general equation for the $m_k \rightarrow m_l$ manifold becomes

$$\begin{aligned} \frac{d}{dt} \rho_{kl}(t) = i \left[\sum_r \rho_{kr}(t) H_{rl} - \sum_i H_{ki} \rho_{il}(t) \right] \\ + k \left[\sum R_{kn} \rho_{nm}(t) (R^{-1})_{ml} - \rho_{kl}(t) \right] - \frac{\rho_{kl}(t)}{T_2} \end{aligned} \quad (11)$$

These equations can be cast into the following matrix form

$$\frac{d}{dt} \boldsymbol{\rho}(t) = \mathbf{L} \boldsymbol{\rho}(t) \quad (12)$$

where $\rho(t)$ is the vector of the $\rho_{kl}(t)$ quantities. The formal solution of $\rho(t)$ then becomes

$$\rho(t) = \exp(\mathbf{L}t)\rho(0) = \mathbf{T} \exp(\mathbf{\Lambda}t)\mathbf{T}^{-1}\rho(0) \quad (13)$$

where $\mathbf{\Lambda}$ is the diagonal matrix of the eigenvalues of $\mathbf{L}$ and $\mathbf{T}$ the matrix of its eigenvectors. From equation (10), it follows that the dimensions of the blocks corresponding to the $m = 0$ to $m = \pm 1$ or $m = \frac{1}{2}$ to $m = -\frac{1}{2}$ transitions for $N = 6, 7$, and 8 become $300, 1225$, and 3920 , respectively, rendering the calculation of such spectra rather time-consuming and prone to roundoff errors even on large mainframe computers.

Symmetry considerations can often be helpful in factorizing the blocks.^{16,17} To do so, the $\rho_{kl}(t)$ terms are calculated in bases of symmetry adapted linear combinations of spin product functions belonging to irreducible representations of the symmetry group of the static molecule.¹⁸ This reduces the dimension of the blocks to just the number of allowed transitions which depending on the symmetry of the molecule can be considerably smaller than given by equation (10). Further factorization is provided by the fact that the exchange operator usually couples only between a limited number of representations, in fact only between those representations that induce the same irreducible representation of the symmetry group of the exchange-averaged Hamiltonian.¹⁶ They can readily be determined by correlation diagrams relating the symmetries of the two groups. These symmetry considerations have in many cases very effectively reduced the size of the matrices that need be solved. For example, in the case of the bondshift reaction of cyclooctatetraene, the largest matrix that need be diagonalized in order to calculate the proton NMR spectrum in a liquid crystalline solution is 3920×3920 , while when symmetry considerations are included it reduces to 224×224 .

3 EXPERIMENTAL ASPECTS

3.1 Liquid Crystalline Solvents

So far only thermotropic nematic phases with positive anisotropic magnetic susceptibility, $\Delta\chi > 0$, i.e. which align with their director parallel to the magnetic field, have been used as solvents for dynamic NMR studies. The nematic phase is usually very fluid and consequently yields sharp-line spectra for dissolved solute molecules. The samples are contained in long cylindrical tubes as for high-resolution NMR of isotropic liquids. If a permanent magnet or an electromagnet with the magnetic field perpendicular to the tube axis is used, it is not allowed to spin the sample because the spinning smears out the director orientation and causes broadening of the spectrum. However, for superconducting magnets where the magnetic field is parallel to the sample axis, spinning usually sharpens the lines and increases the spectral resolution. The choice of solvent depends on the solubility of the solute, its degree of ordering, and the desired temperature range for the measurements. The solute concentrations range between 1–10 wt.%. Addition of solute usually reduces the clearing temperature but on the other hand it also often facilitates supercooling. Table 1 lists some common liquid crystals used in dynamic NMR studies with their nematic ranges.

For proton (and ^{13}C), NMR background signal may also be a consideration in the choice of solvent. For certain solutes, such as polar or hydroxylic compounds, lyotropic nematic phases may be the preferred choice as a solvent, but these have so far not been used for dynamic studies. Compounds exhibiting the uniaxial smectic A phase may also serve as adequate solvents. This phase, once aligned, for example, by cooling from a nematic or an isotropic phase within a magnetic field, will remain aligned in the sample holder even if rotated with respect to the field.¹⁹ This allows reduction of the frequency range of the spectrum if a small sweep width is desired. Smectic phases are however usually more viscous than nematic and in the presence of solutes often undergo phase separation.

3.2 NMR Measurements

Most dynamic NMR studies in liquid crystalline solvents have been performed on protons, carbon-13, and deuterons.^{20–38} The proton spectra are dominated by dipolar interactions and usually span several kHz. Carbon-13 dynamic studies have so far only been made^{24,25} under proton decoupling so that the spectrum depends on the chemical shift anisotropy which is of the same order as that of the isotropic shift in normal liquids. For deuterium NMR the dominant effect on the spectrum is due to the quadrupole interaction, which depending on the motional constants of the solute may extend up to several tens of kHz.

When the frequency range does not exceed about 5–10 kHz, adequate spectra can be obtained by single pulse experiments. For wider frequency ranges, echo experiments are required. This is particularly true for deuterium NMR, where the method of choice is that of quadrupole echo.³⁹ In such experiments the observed lineshape will depend on the time intervals between the pulses in the sequence. This is taken into account⁴⁰ in the simulation by repeated application of equation (13) for the time intervals, where the magnetization evolves freely and performing proper transformations of the density operators representing the rf pulses.

Temperature stability and homogeneity are crucial for obtaining high-resolution spectra. Because of the sensitivity of the orientational order to temperature, small gradients may cause excessive line broadening and corresponding loss of resolution. Imperfect alignment may also be a source for loss of resolution. This is caused by the fact that different domains have slightly different orientations and accordingly slightly different splittings. The effect is often manifested by progressive line broadening for peaks which are further removed from the spectrum center.

4 APPLICATIONS TO SPIN $I = \frac{1}{2}$ NUCLEI

Several applications of high-resolution proton NMR in liquid crystalline solutions have been published and here we describe two such cases. Dynamic ^{13}C spectra recorded under proton decoupling will also be reviewed. The emphasis is on systems for which kinetic information was derived from a lineshape analysis, rather than on dynamic equilibria between species in the extreme fast regime.

Table 1 Nematic Liquid Crystals Used as Solvents for NMR Studies of Solute Molecules

Brand name or acronym	Chemical name and/or composition	Nematic range (°C)
DHAB	4,4'-dihexyloxyazoxybenzene	84–127
TBBA	terephthalaldehyde-bis(4- <i>n</i> -butylaniline)	199–233
S 1131 BCH	<i>trans</i> -4-pentyl-1-(4'-cyanobiphenyl-4)-cyclohexane	96–222
10836	<i>p</i> -(<i>p</i> -ethoxyphenylazo)phenyl crotonate	109–194
Phase V	eutectic mixture of (two isomers each): <i>p</i> -ethoxy- <i>p</i> '-butyloxyazoxybenzene <i>p</i> -methoxy- <i>p</i> '-butyloxyazoxybenzene	5–75
ZLI 2452	mixture of derivatives of cyanophenylcyclohexane, cyanobiphenylcyclohexane, and unspecified esters	–40–110
ZLI 2142	—	–40–85
1565 TNC	mixture of derivatives of phenylcyclohexane and biphenylcyclohexane	–20–85
E8	mixture of derivatives of cyanobiphenyls	–12–72
Nematic mixture	several undisclosed mixtures by Kodak	5–105

4.1 Ring Inversion of *s*-Trioxan

The rate of the ring inversion of *s*-trioxan (Scheme 1) was studied by proton NMR in isotropic solutions.⁴¹ The chemical shift difference between the axial and equatorial protons and their spin–spin coupling are quite small (0.093 ppm and 6.3 Hz, respectively), while the rate of the process at room temperature is rather high. It was therefore necessary to cool the solutions to below –50 °C to obtain dynamic spectra. When the compound is dissolved in a nematic

solvent the spectrum is dominated by the dipolar interactions and its spectral width is considerably larger. Above about 70 °C it exhibits sharp peaks with splittings corresponding to the average dipolar interaction of the two conformations.⁴² However on cooling to room temperature and below, the lines broaden because the exchange rate becomes of the order of the dipolar interactions.²² Examples of spectra are shown in Figure 1. Note that the spectra were recorded in two different nematic solvents which give different background signals. The

Figure 1 Left: Experimental proton NMR spectra of solutions of *s*-trioxan in liquid crystalline solvents at various temperatures. The solvent used was phase V (2.8 wt.%), except for the 79 °C spectrum which corresponds to a 2.0 wt.% solution in DHAB. Note the different background signals for the two liquid crystal solvents. Right: Corresponding simulated spectra, calculated using the indicated rate constants and the magnetic parameters given in Table 2 with a fixed motional constant $C_{3z^2-r^2}^2 = -0.2$

Scheme 1

Table 2 Parameters Used in the Simulation of the *s*-Trioxan Spectra in Figure 1

$J_{14} = 6.3 \text{ Hz}$	$D_{12} = D_{13} = D_{23} = C_{3z^2-r^2}^2 3941.6 \text{ Hz}$
$\sigma_{ae} = 0.093 \text{ ppm}$	$D_{14} = D_{25} = D_{36} = C_{3z^2-r^2}^2 (-9651.26) \text{ Hz}$
	$D_{45} = D_{56} = D_{46} = C_{3z^2-r^2}^2 775.59 \text{ Hz}$
$D_{15} = D_{16} = D_{24} = D_{26} = D_{34} = D_{35} = C_{3z^2-r^2}^2 499.28 \text{ Hz}$	

spectra were simulated using equation (11) with magnetic and kinetic parameters as given in Table 2 and in Figure 1. For simplicity a fixed motional constant was used for displaying the calculated spectra. The dipole–dipole, indirect spin–spin, and chemical shift interactions were determined from low-temperature spectra in isotropic solutions and high-temperature spectra in liquid crystalline solvents. The anisotropic chemical shift and the anisotropic indirect spin–spin coupling were neglected. Since the molecule has threefold symmetry only one motional constant, $C_{3z^2-r^2}^2$, is required. Its value can be obtained from the line splittings, in particular from the so-called dynamically invariant lines, i.e. lines that remain sharp throughout the dynamic range. These lines correspond to transitions that are not modulated (or nearly not modulated) by the dynamic process. Such lines are the two $\pm 1 \rightarrow 0$ pairs of A_2 symmetry clearly seen in the low-temperature spectra of Figure 1. Inspection of the eigenfunctions²² between which these transitions occur shows that the exchange-induced permutation of nuclei does not change the dipolar interactions of either the initial or final states. The chemical shift on the other hand is modulated by the exchange, but the effect is small and is averaged out already at much lower temperatures than those for which spectra are depicted in Figure 1.

The derived rate constants for the ring inversion reaction are plotted in Figure 2. The figure demonstrates one of the main advantages of the method, i.e. the large dynamic range over which measurements can be made. The lower bound of the dynamic range (10^4 s^{-1}) in this experiment was set by the lack (at the time) of suitable nematic liquids for high-resolution measurements below -20°C . Also depicted in Figure 2 are the results obtained in an isotropic solvent. These correspond to rates which are orders of magnitude slower than those obtained in the nematic solvent and span a much smaller dynamic range. It may be seen however that both sets of data fit a single Arrhenius line. This indicates that within the accuracy of the experiment the kinetic parameters for the reaction are not very sensitive to the solvent, not even on going from an isotropic to a nematic solvent. This is not surprising for a ring-inversion process, since its rate is predominantly determined by the internal coordinates of the molecule. In other cases, where solute–solvent interactions play a role or for bimolecular reactions where ordering effects are important, the situation may be different.

**Figure 2** Arrhenius plot of the rate constant for the ring inversion of *s*-trioxan in liquid crystalline (circles) and isotropic (triangles) (Freon) solvents. The circles above 60°C correspond to solvent DHAB while those below to phase V

4.2 Bond Shift in Cyclooctatetraene (COT)

As a second example we consider the bond shift process in COT (Scheme 2). This molecule has D_{2d} symmetry rendering all eight protons of the molecule equivalent. Consequently the proton NMR spectrum in an isotropic solvent consists of a single line and is not useful for dynamic measurements. The bond shift reaction could therefore only be studied in substituted molecules and in a qualitative manner from the ^{13}C spectrum.^{43,44} The proton NMR spectrum of COT in a liquid crystalline solvent on the other hand is highly structured, reflecting the dipolar interactions between all protons in the molecule and exhibits dynamic effects as the temperature is raised from below -20°C to well above 100°C .²¹ Examples of spectra are depicted in Figure 3. The ‘static’ spectrum at -25°C could readily be interpreted with the parameters summarized in Table 3. On heating to above -25°C line broadening sets in and at room temperature only a number of invariant (or almost invariant) lines are observed. Above 100°C the spectrum coalesces yielding at 170°C a pattern corresponding to the averaged dipolar interactions. Simulation of such dynamic spectra would require, without the use of

Scheme 2

Figure 3 Left: Experimental proton NMR spectra of COT in liquid crystalline solvents at different temperatures. The solvents were: for -25°C to 20°C , phase V; for 40°C , 'Nematic Mixture'; 70°C and 105°C , DHAB; and for 170°C , TBBA. Right: Simulated spectra calculated with the indicated rate constants and the magnetic parameters given in Table 3. A fixed motional constant was used for all the simulated spectra. The spacings between the markers on the left are 500 Hz for the bottom four spectra, 250 Hz for the next three and 125 Hz for the topmost one. On the right, the spacings are 1000 Hz for the bottom four traces and 500 Hz for the four upper ones

symmetry, the diagonalization of matrices as large as 3920×3920 . When symmetry considerations are included¹⁶ and group theoretical methods are applied to factorize the matrices, the largest block becomes 224×224 . This in fact made the problem solvable in practice,²³ as shown by the simulated spectra in the right column of Figure 3.

In the original work on the NMR spectrum of COT in liquid crystalline solutions²¹ dynamic information was derived from proton spectra of almost but not completely deuterated COT. The isotopic mixture contained a relatively large fraction of $\text{C}_8\text{D}_6\text{H}_2$ isotopomers, each yielding at slow exchange a single doublet. From the initial broadening of the peaks and from the width of the lines in the fast exchange region, estimates

Table 3 Magnetic Parameters of COT used in the Simulation of the Dynamic Spectra Depicted in Figure 3

D_{12}	-1620.3
$D_{13} = D_{17}$	-103.8
D_{14}	-84.5
D_{15}	-147.5
D_{16}	-206.3
D_{18}	+960.9
J_{12}	11.8

of the rate parameters for the bond shift process were derived. The use of such incompletely deuterated samples to obtain simplified proton spectra was found helpful in many structural studies of solute molecules.^{45–48} To eliminate broadening due to dipolar interactions with the deuterons, a special decoupling technique was designed involving saturation of the deuterium double quantum transition.^{45,46} This requires much less rf power and eliminates sample heating problems.

4.3 Hindered Rotation Measurements

Dynamic NMR has also been applied to natural-abundant ^{13}C of solute molecules dissolved in liquid crystals as demonstrated by Fung et al.²⁴ Since such spectra are extremely weak and are often masked by the more intense solvent peaks, they were recorded under proton decoupling conditions. The spectra are then essentially identical to those in isotropic solutions except that the chemical shift is modified by the solute ordering. To reduce the interference effect of the solvent signals, special spin echo sequences were used to take advantage of the shorter T_1 values of the nematic solvent carbons, but even then special solvents with ^{13}C windows at the solute frequencies had to be used.

Further simplification may be achieved by using magic angle spinning.²⁵ For $\Delta\chi > 0$ solvents the director aligns along the spinning axis and the spectrum becomes identical to that in an isotropic solvent. Under these conditions, there is no advantage in using a liquid crystalline solvent, unless of course one wishes to study the effect of ordering on the dynamic process. The method was applied to several systems exhibiting hindered rotations; 4-(dimethylamino)pyrimidine and 6-(dialkylamino)fulvenes. The main conclusion of the work confirms that within the experimental accuracy the ordering by the nematic solvent does not affect the kinetic parameters of the process.

5 MULTIPLE QUANTUM DYNAMIC NMR FOR SPIN $I = \frac{1}{2}$ NUCLEI

The proton NMR spectra in liquid crystalline solvents for molecules with 10 or more hydrogens are so rich in lines that they become structureless with few features that can be used for quantitative analysis. The difficulty can partially be resolved by employing the method of multiple quantum spectroscopy. In such experiments one displays $\Delta m > 1$ spectra which involve less transitions than the corresponding ordinary $\Delta m = 1$ spectra, and are therefore better resolved and more convenient for comparison with calculations.⁴⁹ As for

Figure 4 Experimental 2D fourth quantum order contour plot for a solution of *s*-trioxan (2.7 wt.%) in phase V at 17 °C using the SMQ experiment. The one-dimensional spectra along ν_1 and ν_2 are skyline projections and correspond respectively to fourth and single quantum order transitions

single quantum spectra these also exhibit line broadening and coalescence effects. They cannot be detected by ordinary pulse NMR, but can be obtained by several indirect ways which usually involve 2D methods. Two methods were considered for dynamic proton NMR in liquid crystalline solvents. The time proportional phase increment (TPPI) sequence⁵⁰ was employed for simulating²⁶ dynamic multiple quantum spectra and, subsequently, a simpler version⁵¹ which allows recording a particular single multiple quantum (SMQ) spectrum was used.²⁷ We refer to the literature^{26,27} for the theoretical background and confine ourselves here to briefly reviewing experimental results obtained in liquid crystalline solutions.

In Figure 4 a 2D plot of the proton SMQ spectrum of a solution of *s*-trioxan recorded at 17 °C is displayed²⁷ together with skyline projections along ν_1 (the evolution coordinate) and ν_2 (the detection coordinate). The latter is a $\Delta m = 1$ spectrum but the much simpler ν_1 projection corresponds to the fourth quantum order. Similar fourth quantum projection spectra recorded at different temperatures are presented in Figure 5. These are compared with simulated spectra which were computed by two methods; exact calculation employing the full density matrix formalism and approximate methods. The latter are the density matrix analogs for the slow (bottom trace) and fast (all other traces) exchange regimes. No adjustable parameters were used in the calculations (except for the order parameter), rather the known rate constants and magnetic parameters from earlier studies were adopted. As may be seen, the fit of the experimental and simulated spectra is quite satisfactory. It should be noted however that despite the simple appearance of the MQ spectra their simulations are as complicated as those for the single quantum spectra. This is so because for the calculations it is necessary to follow the evolution of a multitude of coherences. Fortunately,

approximate methods exist²⁶ that are much simpler and as may be seen in Figure 5 they result in spectra very similar to those calculated by the exact method.

6 DYNAMIC NMR FOR SPIN $I = 1$ NUCLEI

Of the nuclei with spin $I = 1$, deuterium is the most important for dynamic NMR studies in nematic solvents. However due to its low natural abundance it is necessary to work with isotopically enriched samples. This might require special skills, but techniques are available that allow complete or selective deuteration of many compounds.⁵² The method has several advantages; the spectrum is free of background signals and is usually very simple. The dipolar interactions between the deuterons or with other nuclei (protons) are usually within the linewidths, and the structure of the spectrum is predominantly due to the much larger quadrupole interaction. For spin $I = 1$ nuclei, this corresponds to a single doublet for each type of nucleus, and thus the deuteron spectrum of a deuterated solute in a nematic solvent consists of a number of doublets according to the number of inequivalent deuterons in the molecule. The simulation of dynamic spectra then requires only the solution of Bloch–McConnell type equations rather than the full density matrix equations. In the absence of chemical shift effects, the spectrum of the $m = -1$ to $m = 0$ manifold is the mirror image about the center frequency of the $m = 0$ to $m = +1$ manifold. A third advantage is the large dynamic range that can be studied by deuterium NMR. Since the splitting can be as high as several dozens of kHz, the upper limit of the dynamic range may be considerably higher than that for protons.

6.1 Ring Inversion in Cyclohexane and *p*-Dioxan

As a simple example where the advantages of dynamic deuterium NMR in nematic solvents are well demonstrated, consider the ring inversion process in cyclohexane- d_{12} (C_6D_{12}) (Scheme 3). Experimental spectra²⁸ are depicted in the left column in Figure 6. At low temperatures the spectrum consists of two doublets due to the axial (outer doublet) and equatorial (inner doublet) deuterons with a relative splitting of ~ 3 . The quadrupole interaction for aliphatic deuterons are nearly constant at $\nu_Q^s \approx 125$ kHz (as compared to ~ 140 kHz for aromatic deuterons) with cylindrical symmetry about the C–D bond. Accordingly the average quadrupole splitting for a molecule with threefold symmetry, such as cyclohexane, will be proportional to $\nu_Q^s \frac{1}{2}(3 \cos^2 \beta - 1)$ where β is the angle between the C–D bond and the molecular symmetry axis. For the axial and equatorial deuterons in cyclohexane, this corresponds to $\langle \nu_Q^{ax} \rangle / \langle \nu_Q^{eq} \rangle \sim -3$ as observed experimentally. In the dynamic spectra the opposite signs of the $\langle \nu_Q \rangle$ quantities is reflected in the mixing of the high-frequency axial

Scheme 3

Figure 5 Experimental (left) and calculated (center and right) fourth order quantum spectra of *s*-trioxan solutions in phase V. The experimental spectra were obtained as in Figure 4, the spectra in the middle column were calculated by the exact density matrix formalism, those in the right column were calculated by approximate methods

Figure 6 Experimental (left) and simulated (right) deuterium NMR spectra of cyclohexane- d_{12} (3.6 wt.%) in phase V. The overall frequency range corresponds to 83.3 kHz for the lowest three traces and 50.0 kHz for the upper four

peak with the low-frequency equatorial peak and vice versa. This is clearly observed in the experimental spectra depicted in Figure 6 and in the corresponding simulated traces. The spectra correspond to inversion rates ranging from 10^3 s^{-1} to almost 10^6 s^{-1} , and when semilogarithmically plotted as a function of the inverse absolute temperature a straight Arrhenius line is obtained which extrapolates perfectly through the results obtained in isotropic liquids at much lower temperatures.⁵³ In the simulation of the spectra the order parameter, $C_{3z^2-r^2}^2$, must be known. In the low- and high-temperature regions, where sharp peaks are observed, this parameter can be calculated from the line splitting and by interpolation the values at the intermediate range can be derived.²⁸

As a second example we consider the case of *p*-dioxan (Scheme 4). This molecule has C_{2h} symmetry and therefore three motional constants are required to describe its orientation in a liquid crystalline solvent. The average quadrupole splitting is given by

$$\langle \nu_Q^i \rangle = \nu_Q^s \sqrt{\frac{3}{5}} \left[\frac{1}{\sqrt{3}} C_{3z^2-r^2}^2 \frac{1}{2} (3 \cos^2 \beta^i - 1) + C_{x^2-y^2}^2 \frac{1}{2} \sin^2 \beta^i \cos 2\alpha^i - C_{xy}^2 \frac{1}{2} \sin^2 \beta^i \sin 2\alpha^i \right] \quad (14)$$

where β^i and α^i are the polar and azimuthal angles of the C-Dⁱ bond in the molecular coordinate system x, y, z with

Scheme 4

z perpendicular to the symmetry plane of the molecule. The motional constants are independent and their ratios vary with temperature and from solvent to solvent. Therefore there is no a priori relation between the quadrupole splittings of the axial and equatorial deuterons as is in cyclohexane. In particular their relative sign can be both positive and negative.

The *p*-dioxan molecule undergoes ring inversion in a similar fashion to cyclohexane⁵³ and the reaction was studied by deuterium dynamic NMR in two nematic solvents, phase V and 1565 TNC.²⁹ Experimental spectra are shown in the left columns of Figure 7. As may be seen, their evolution with temperature is quite different and this has been interpreted as due to different relative signs of the axial and equatorial

Scheme 5

quadrupole interactions (same signs in phase V and opposite signs in 1565 TNC). When this effect is taken into account, satisfactory simulation of both sets of spectra are obtained as shown in the right columns of Figure 7. The derived rate constants for the ring-inversion process were found to be identical in both solvents.

The spectra shown above for C_6D_{12} and $C_4O_2D_8$ (Figures 6 and 7) were recorded by single pulses and are therefore distorted due to the dead-time effect. In subsequent works this problem was resolved by using the quadrupole echo method. The spectrum is then also a function of the time interval between the pulses and this must be included in the simulation.⁵⁵

Figure 7 (a) Experimental and simulated deuterium NMR spectra of *p*-dioxan- d_8 dissolved in phase V. The overall frequency scale is 50 kHz for the bottom three spectra and 20 kHz for the top two. In the simulation identical signs of the quadrupole interactions were assumed for the axial and equatorial deuterons. (b) Same as in (a) but for a solution in 1565 TNC. The overall scale is 100 kHz for the bottom three traces and 20 kHz for the top two. In the simulation, opposite signs for the axial and equatorial deuterons were assumed

6.2 Cope Rearrangement in Bullvalene

Bullvalene undergoes fast Cope rearrangement (Scheme 5) and this process has been extensively studied by 1H and ^{13}C NMR in isotropic solutions.⁵⁴ The reaction is highly degenerate and results in complete equivalence of all the carbons and all the hydrogens in the molecule. Proton spectra of bullvalene dissolved in a nematic solvent were also recorded⁵⁶ but only at high temperatures where they correspond to the fast exchange limit. More extensive studies involving liquid crystalline solutions were made by deuterium NMR.³⁰ At low temperatures the spectrum consists of four doublets with relative intensities 3:3:3:1 [see Figure 8(a)]. The identification of the outer peaks with deuterium number 4 is straightforward while the other peaks were identified from the known structure of the molecule. The spectrum shows a small asymmetry which is due to the fact that the olefinic deuterons have a slight high-frequency shift relative to the aliphatic ones. At high temperatures [upper trace in Figure 8(a)] the spectrum coalesces into a single doublet, reflecting the fact that all deuterons become equivalent. In the intermediate temperature range typical dynamic spectra are observed, Figure 8(b), that could readily be simulated as shown in Figure 8(c). The deuterium quadrupolar couplings, ν_Q^i , used for the simulation of the dynamic spectra are listed in Table 4 in units of the largest splitting, ν_Q^4 . The good fit between the experimental and simulated spectra confirms the high degeneracy of the Cope rearrangement. A more direct confirmation of the kinetic pathway was obtained by the two-dimensional exchange method described in the next section.³³

Table 4 Deuterium Quadrupolar Couplings, ν_Q^i , Used in the Simulation of the Dynamic Spectra of Bullvalene [Figure 8(b)], in Units of the Largest Splitting, ν_Q^4

i	1	2	3	4
ν_Q^i/ν_Q^4	0.727	-0.401	0.271	1.0

Figure 8 (a) Experimental deuterium NMR spectra of bullvalene-*d*₁₀ dissolved in ZLI 2452 (3.8 wt.%) at -5 °C (lower trace) and in DHAB (4.7 wt.%) at 114.3 °C (upper trace). The diagram at the top indicates the different orders of exchange by the Cope rearrangement. Double arrow, full line, and dashed line correspond to first-, second-, and third-order exchanges. (b) Experimental dynamic NMR spectra of bullvalene-*d*₁₀ in phase V (5.7 wt.%) at the indicated temperatures. (c) Simulated dynamic spectra calculated using the indicated rate constants and the relative quadrupole interactions given in Table 4. For each spectrum, a suitable motional constant was chosen³⁰

7 TWO-DIMENSIONAL EXCHANGE NMR SPECTROSCOPY FOR SPIN $I = 1$ NUCLEI

Two-dimensional (2D) exchange NMR was introduced by Jeener et al. to study slow exchange processes for spin $I = \frac{1}{2}$ nuclei.⁵⁷ The method was subsequently extended to deuterons ($I = 1$) in solids and ordered systems in general by Spiess and collaborators.^{58–60} It is most useful in the dynamic window for which $1/T_1 \lesssim k < 1/T_2$ and has also found interesting application in liquid crystalline solutions of deuterated solutes. Some of these will be described below.

The basic scheme of the experiment consists of three pulses (Scheme 6).³¹ Following the first 90° pulse (P_1) which takes the magnetization to the transverse plane, the various nuclei precess according to their quadrupole interactions and are thus phase-encoded. A second θ pulse (P_2) then produces either Zeeman or quadrupole order depending on the relative phases ($\phi_1 - \phi_2$) of the two pulses. These longitudinal magnetizations are allowed to undergo exchange during a preset mixing time, τ_m , following which a third pulse (P_3) takes them back to the transverse plane and the signal is detected as a function of the detection period t_2 . To obtain pure 2D

exchange spectra, signals from Zeeman and quadrupole order experiments are combined with appropriate relative intensities, so as to eliminate nonexchange off-diagonal peaks. Two-dimensional Fourier transformation then produces a 2D map with peaks corresponding to the one-dimensional spectrum along the main diagonal and exchange cross peaks off the main diagonal. These cross peaks link between sites i, j which interchange by the exchange process. Their intensity is proportional to

$$I_{ij} = P_i [\exp(kK\tau_m)]_{ij} \exp(-\tau_m/T_1) \quad (15)$$

where P_i is the equilibrium population of site i , and k and K are respectively the rate constant and the exchange matrix for the process. The experiment has several important advantages; measurements can be made in a dynamic range inaccessible by the lineshape method; the cross peaks directly identify the interchanging sites and thus the mechanistic pathway of the process; the cross peaks provide information on the relative signs of the quadrupole interactions of the interchanging sites, and from their evolution with τ_m kinetic parameters may be derived.

Scheme 6

7.1 Peak Assignment and Relative Signs of Quadrupole Interactions

An example where some of the points mentioned in the last paragraph are demonstrated is that of *p*-dioxan-*d*₈ already discussed²⁹ in Section 6.1. It was pointed out there that the signs of the quadrupole interactions of the axial and equatorial deuterons are the same when *p*-dioxan is dissolved in phase V and the opposite in 1565 TNC. This is clearly seen in the exchange 2D spectra³¹ in Figure 9, where for phase V the cross peaks link separately the high-field and the low-field signals of the axial and equatorial deuterons, while in 1565 TNC a low-field axial peak is linked with a high-field equatorial peak and vice versa.

An application of the 2D exchange method which was essential for the peak assignment, is that of perdeuterated *cis*-decalin.³⁴ The molecule undergoes ring inversion (Scheme 7)⁶¹ and in liquid crystalline solutions exhibits temperature dependent dynamic spectra as shown in the left column of Figure 10. To simulate the spectra it is necessary to identify the peaks with particular deuterons in the molecule, or at least to identify the interchanging pairs of peaks. This can readily be done for deuterons 1,1' which are bonded to the tertiary carbons and remain invariant to the dynamic process. However for all other lines the assignment is not trivial. Since the molecule has *C*₂ symmetry, three motional constants are required to describe the ordering of the molecules [equation (14)] and the assignment cannot be made simply from a knowledge of the molecular structure. The problem was resolved by 2D exchange spectroscopy.³⁴ A 2D spectrum recorded at -5 °C is shown in Figure 11 where cross peaks linking pairs of diagonal signals are clearly observed. Although this does not completely assign the peaks, it does identify the signals which interchange by the ring-inversion process. Using this information, dynamic spectra could be simulated which satisfactorily reproduce the experiments as shown in the right-hand column of Figure 10. Other examples where 2D exchange provided assignment and even identified hidden peaks masked by strong signals include 1,1- and 1,4-dimethylcyclohexane.³⁸

Figure 9 Two-dimensional deuterium exchange spectra on solutions of *p*-dioxan-*d*₈ dissolved in phase V (left) and 1565 TNC (right). The spectra were taken at -43 °C with a mixing time $\tau_m = 1$ ms. Note that the signs of the quadrupole interactions of the two exchanging deuterons is the same in phase V and the opposite in 1565 TNC

Scheme 7

7.2 Cope Rearrangement In Bullvalene: Higher Order Cross Peaks

Most examples of monomolecular exchange phenomena involve twofold degeneracy, i.e. interchange between two configurations. In the 2D exchange spectrum this is manifested by cross peaks linking separate pairs of lines. The bullvalene molecule provides an example of a high degree of degeneracy where a diagonal peak can be linked by the exchange to more than one other signal. Consequently at longer mixing times, when two or more exchange steps occur, higher order cross peaks between signals not directly connected by the exchange process may show up.

This is demonstrated³³ in the 2D exchange spectra of bullvalene depicted in Figure 12. For a mixing time of 2 ms only first-order cross peaks are observed [see diagram in Figure 8(a)], i.e. between peaks directly linked by a single Cope rearrangement. At 5 ms an additional second order cross peak appears (1, 2) which is linked by two successive rearrangement steps, while at 10 ms even a third-order cross peak (4, 2) may

Figure 10 Experimental (left) and simulated (right) deuterium spectra of *cis*-decalin-*d*₁₈ in liquid crystalline solvents. The bottom three traces correspond to the solvent ZLI 2452 while the upper four to S 1131 BCH. The separation between the frequency markers corresponds to 10 kHz for the bottom three traces and to 5 kHz for the top four

Figure 11 A two-dimensional deuterium-exchange spectrum of a solution of *cis*-decalin-*d*₁₈ in ZLI 2452 at -5°C . The dashed lines identify the interchanging peaks due to ring inversion. The assignment of the peaks based on the 2D spectra and other considerations are indicated on the 1D spectrum above

be identified. Expanding equation (15) in powers of τ_m gives

$$I_{ij} = P_i[\delta_{ij} + kK\tau_m + \frac{1}{2}k^2K^2\tau_m^2 + \frac{1}{6}k^3K^3\tau_m^3 + \dots]_{ij} \quad (16)$$

where for the case of bullvalene

$$K = \begin{bmatrix} -1 & 0 & 2/3 & 1/3 \\ 0 & -1/3 & 1/3 & 0 \\ 2/3 & 1/3 & -1 & 0 \\ 1 & 0 & 0 & -1 \end{bmatrix} \quad (17)$$

Computation of K^2 and K^3 shows that indeed the element 1, 2 which is zero in K is nonzero in K^2 while an entry at 4, 2 appears only at K^3 and higher powers of K . In the short τ_m approximation, second- and third-order peaks should therefore increase as τ_m^2 and τ_m^3 , while first-order cross peaks (and the diagonal peaks) should increase (decrease) linearly. This is indeed confirmed experimentally.

8 DYNAMIC ECHO TRAIN EXPERIMENTS

In some cases dynamic spectra can only be obtained in the fast exchange regime, e.g. when the rate is fast and the activation energy too low to reduce it effectively to the intermediate and slow-exchange limit by cooling. Kinetic data can then be obtained by transverse relaxation studies but the

Figure 12 Two-dimensional deuterium exchange spectra of bullvalene- d_{10} dissolved in ZLI 2452 at 5°C for several mixing times as indicated in the figure. The dashed lines connect first-, second-, and third-order cross peaks in respectively the upper, middle and bottom spectra

Figure 13 Semilog plots of the echo intensity versus time in quadrupole echo train experiments performed on a solution of C_6D_{12} in phase V (7 wt.%) at 12.2°C for different pulse repetition rates as indicated

calculation requires knowledge of the magnetic interactions. When these are not known, ordinary relaxation data are not very useful. However when the transverse relaxation is measured by the Carr–Purcell sequence, or for spin $I = 1$ in liquid crystalline solvents by its quadrupole echo train analog, a determination of the rate constant can still be made if the time interval, τ , between the pulses is of the order of the mean lifetime between exchanges. In the fast-exchange regime, the transverse relaxation rate, as measured by the echo decay, is then also a function of the ratio of the exchange and pulse repetition rates.⁶² For deuterons jumping between two sites of equal populations the contribution to the decay rate of the echoes in a quadrupole echo train experiment becomes^{32,35}

$$\frac{1}{T_{2e}} = \frac{(\Delta\omega_Q)^2}{8k} \left[1 - \frac{\tanh(2k\tau)}{2k\tau} \right] \quad (18)$$

where $\Delta\omega_Q = \omega_Q^A - \omega_Q^B$ is the difference between the quadrupole splittings of the nuclei at the two sites.

The method was demonstrated³² for the case of ring inversion of C_6D_{12} in the nematic phase V between 0°C and the clearing temperature. Experimental echo intensities at 12.2°C for different time intervals between pulses are depicted in Figure 13 and the dependence of the decay rate, $1/T_{2e}$ on the pulse repetition rate, $1/\tau$, is plotted in Figure 14 for several temperatures. Analysis of these data in terms of equation (18) yields results for k that are in good agreement with those derived from the ordinary lineshape analysis.

The method was subsequently extended to the intermediate and slow-exchange regime³⁵ and although not very often used it has been successfully applied to study the self-diffusion in the plastic phase of succinonitrile.⁶³

1 INTRODUCTION

Because of the ubiquitous presence of the carbon atom in organic compounds, ^{13}C NMR has been widely used to study liquid, liquid crystalline, and solid samples. The application of ^{13}C NMR to study liquid crystals offers important information that complements that obtained from proton and deuterium NMR experiments. The most important parameters obtained in ^{13}C NMR studies of liquid crystals are anisotropic ^{13}C chemical shifts, ^1H - ^{13}C dipolar coupling constants, and ^{13}C relaxation times. They will be reviewed in this article.

2 ANISOTROPIC ^{13}C CHEMICAL SHIFTS IN LIQUID CRYSTALS

For macroscopically oriented liquid crystal samples, the major advantage of ^{13}C NMR is the simplicity of the spectra. With broadband proton decoupling, the ^{13}C spectra of liquid crystals usually show resolvable peaks which can be assigned to individual carbon atoms, similar to the case of isotropic samples. However, because of the presence of ^{13}C chemical shift anisotropy, the chemical shifts of the observed signals (δ^{obs}) are often considerably different from those in the isotropic state (δ^{iso}):

$$\begin{aligned}\delta^{\text{obs}} &= \delta^{\text{iso}} + \delta^{\text{aniso}} \\ &= \delta^{\text{iso}} + \frac{2}{3}S_{zz}[\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy})] \\ &\quad + \frac{1}{3}(S_{xx} - S_{yy})(\sigma_{xx} - \sigma_{yy}) \\ &\quad + \frac{2}{3}S_{xy}\sigma_{xy} + \frac{2}{3}S_{xz}\sigma_{xz} + \frac{2}{3}S_{yz}\sigma_{yz}\end{aligned}\quad (1)$$

where the S_{ij} are components of the order parameter matrix, and the δ_{ij} are components of the chemical shift tensor, both being in the same axis system.

The first report on the ^{13}C NMR of liquid crystals was given by Yannoni and Whipple, who studied ^{13}C -enriched CH_3I dissolved in a liquid crystalline solvent.¹ They determined the order parameter S_{zz} of the molecule from its proton spectrum (the other components of the order parameter matrix are zero), and calculated the ^{13}C chemical shift anisotropy $\delta_{zz} - (\delta_{xx} + \delta_{yy})/2$ according to equation (1). Subsequently, similar studies of other small solute molecules have been made, using either enriched or naturally abundant compounds. Examples include acetonitrile,^{2,3} hydrogen cyanide,⁴ benzene,^{5,6} acetylene,⁷ chloroform,³ methyl halides,³ methanol,³ a further study of CH_3I ,⁸ benzonitrile,⁹ halobenzenes,¹⁰ pyridine,¹¹ and diazenes.¹¹ Details of the determination of ^{13}C chemical shift anisotropy using liquid crystalline solvents are discussed by Jokisaari (see *Anisotropy of Shielding and Coupling in Liquid Crystalline Solutions*), and will not be repeated here.

A much more general application of ^{13}C NMR is the investigation of bulk liquid crystals in their natural abundance. The first work of this type was reported by Pines and co-workers, who studied the ^{13}C chemical shifts of 4,4'-azoxyanisole,¹² 4-methoxybenzylidene-4'-*n*-butylaniline (MBBA)¹³ and 4-alkoxyazoxybenzenes¹⁴ as a function of temperature. Fyfe, Lyerla, and Yannoni also demonstrated the significant effect of orientational ordering on the ^{13}C chemical shifts of MBBA, 4,4'-di-*n*-hexyldiphenyldiacetylene, and 4-*n*-octyl-4'-cyanobiphenyl (8CB).¹⁵ By using model compounds to estimate the components of the chemical shift tensors in the molecular axis system, Pines and co-workers calculated the order parameter S_{zz} of the liquid crystals from equation (1), omitting other terms.¹²⁻¹⁴ The method of employing ^{13}C chemical shifts to estimate the order parameters of liquid crystals is rather simple and straightforward, and studies have been made on other systems. Examples include a eutectic mixture of MBBA and 4-ethoxybenzylidene-4'-*n*-butylaniline (EBBA),¹⁶ several chiral smectic C (SmC*) compounds,^{17,18} and 4-cyanobenzylidene-4'-*n*-octyloxyaniline.¹⁹ However, because the ^{13}C chemical shift tensors are highly dependent upon the molecular structure and the nature of substituents, and their principal axis systems do not always coincide with the molecular axis system used to define the order parameters, the values obtained from model compounds may not be very accurate. Thus, the order parameters calculated are only approximations. On the other hand, calculations made by combining the ^{13}C chemical shift data with dipolar and quadrupolar splittings²⁰ give more reliable results.

If a liquid crystal sample is not macroscopically oriented, the ^{13}C spectrum would be a superposition of peaks, showing a 'powder pattern'; if the sample is partially oriented, such as cholesteric or SmC* phases with the helical axes aligned along the magnetic field, the spectra exhibit 'partial powder patterns'. In these cases, information obtained from the ^{13}C spectra is rather limited. An attempt has been made to calculate diffusion constants of two cholesteric mixtures from the lineshapes of their ^{13}C spectra,²¹ but it depends on a number of assumptions and is less reliable than the pulsed field gradient method, which is discussed by Lindblom (see *Liquid Crystalline Samples: Diffusion*).

3 MAS AND VAS

To obtain resolvable peaks in the ^{13}C spectra of liquid crystals, broadband proton decoupling must be used.^{12–15} Because the proton spectra of liquid crystals have wide spectral windows, the decoupler power applied must be considerably larger than that for liquid samples. Excessive decoupler power, however, leads to rf heating, which is an extremely undesirable effect²² because the orientational ordering of liquid crystals is very sensitive to temperature. To alleviate this problem, the MAS (magic angle spinning) and VAS (variable angle spinning) techniques can be used.

With MAS, the ^{13}C linewidths of liquid crystal samples can be greatly reduced even with rather nominal decoupler power.²³ The MAS method has been employed to investigate the conformation of liquid crystal molecules,^{24–26} phase transition,^{18, 27} the rate process of dissolved solute molecules,²⁸ and lipid systems.^{29–32} It should be noted that, because of the fast motions in liquid crystals, cross polarization is effective for static samples,^{12–14} but much less so with MAS.²³ MAS also removes the anisotropic chemical shifts and dipolar couplings, which are often the most interesting aspects of the ^{13}C NMR of liquid crystals.

Like MAS, the VAS technique results in sharp ^{13}C peaks for bulk liquid crystals.^{16, 33} In addition, part of the anisotropic interactions are preserved, offering an advantage over MAS. The principles of the VAS technique are reviewed in a recent article³⁴ and discussed by Courtieu (see *Spinning Liquid Crystalline Samples*). Here, the essential features pertinent to ^{13}C NMR are briefly outlined for the convenience of discussion.

Solid samples with VAS show residual ‘powder patterns’ in the proton-decoupled ^{13}C spectra, because the chemical shift anisotropy is not averaged to zero. On the other hand, even though residual chemical shift anisotropy is present in nematic liquid crystal samples with VAS, the ^{13}C spectra show sharp peaks due to macroscopic alignment of the director.^{16, 33} For a nematic liquid crystal being spun along an axis forming an angle η with respect to the magnetic field B_0 , the macroscopic orientation of the director is determined by a competition between the magnetic torque and the viscous torque. If the spinning rate is high enough, the nematic director of liquid crystals with a positive anisotropy of the magnetic susceptibility ($\Delta\chi > 0$) aligns along the spinning axis for $0^\circ < \eta < 54^\circ 44'$, and aligns perpendicular to the spinning axis for $54^\circ 44' < \eta < 90^\circ$. The alignment with respect to the spinning axis for liquid crystals with $\Delta\chi < 0$ is opposite to liquid crystals with $\Delta\chi > 0$.^{16, 33} Smectic liquid crystals can also be aligned similarly, provided that they are cooled down from the nematic phase while the sample is being spun rapidly.²³

The macroscopic alignment of the director gives sharp peaks in the ^{13}C spectra, with scaled anisotropic chemical shifts expressed by

$$\delta^{\text{obs}} = \delta^{\text{iso}} + \frac{3 \cos^2 \eta - 1}{2} \delta^{\text{aniso}} \quad (2)$$

for parallel alignment, and by

$$\delta^{\text{obs}} = \delta^{\text{iso}} - \frac{3 \cos^2 \eta - 1}{4} \delta^{\text{aniso}} \quad (3)$$

for perpendicular alignment, where δ^{aniso} is the anisotropic part of the chemical shift, which is given in equation (1).

The spectra in Figure 1 illustrate the effect of VAS on the proton-decoupled ^{13}C NMR of 4-*n*-pentyl-4'-cyanobiphenyl (5CB). With the normal condition of $\eta = 0$, the ^{13}C peaks show large shifts [Figure 1(c)] from their isotropic values [Figure 1(a)], and the changes in the chemical shifts of different carbons are related to the corresponding chemical shift tensors. However, the peaks are not very sharp due to incomplete proton decoupling. On the other hand, the proton–proton dipolar interactions are reduced in a VAS experiment, so that much better decoupling can be achieved with a reasonable decoupler power (20–25 kHz). Thus, sharp ^{13}C peaks can be observed, with the anisotropic part of the chemical shifts scaled by the factor $(3 \cos^2 \eta - 1)/2$ [Figure 1(b)].

By taking advantage of the changes in ^{13}C chemical shifts with the alignment of the director, the dynamics of the realignment process of liquid crystals in a magnetic field can be studied with ^{13}C NMR. When the spinning sample is suddenly stopped, the action of the magnetic torque causes the director to realign from being parallel to the spinning axis to being parallel to the magnetic field. Consequently, the ^{13}C spectrum gradually changes from that in Figure 1(b) to Figure 1(c). The chemical shift is related to the angle β formed between the director and the magnetic field by an equation similar to equation (2) for the angle η . The time dependence of β is governed by the relationship^{35, 36}

$$\beta = \tan^{-1}[(\tan \eta) e^{-t/\tau}] \quad (4)$$

where τ is the time constant for the reorientation of the nematic director in the magnetic field. Thus, by using a least-squares fitting of the chemical shift data as a function of time after the rotor stops, the value of τ can be determined.³⁷ Actually, equation (4) is strictly applicable to rigid rods only. However, liquid crystal molecules are flexible and the order parameters of individual molecular segments differ along the long axis. Because the hydrodynamic behavior of liquid crystals is related to their order parameters, the reorientation times for different parts of the molecule need not be the same. For 5CB at room temperature, it was found that $\tau = 8.7$ ms for the aromatic rings and 11 ms for the methyl group.³⁷ The smectic A compound 8CB is much more viscous, and the corresponding τ values are about 300 times longer, being 2.4 and 3.2 s, respectively.³⁷

In the application of VAS to study liquid crystals, a sufficiently high spinning rate must be used to induce macroscopic alignment with respect to the spinning axis (~ 1 kHz at $B_0 = 7$ T for most liquid crystals), and the critical spinning rate is proportional to the square of the magnetic field.^{33, 34} However, the inertial torque tends to oppose the viscous torque and the magnetic torque, and would destroy the alignment at very high spinning rates.³⁴ Therefore, one must be careful to balance the different torques to obtain the desired macroscopic orientation of the liquid crystalline samples.

4 THE EFFECT OF THE LOCAL DIPOLAR FIELD

In Section 2, it was pointed out that in most cases it is difficult to evaluate accurately the order parameters from ^{13}C chemical shifts because the use of equation (1) requires a

Figure 1 Proton-decoupled ^{13}C NMR spectra of 5CB at 75.43 MHz. (a) Isotropic spectrum at 37°C. (b) Anisotropic spectrum at 26°C, with a spinning angle of $\eta = 44.6^\circ$ and a spinning rate of 1.1 kHz. (c) Anisotropic spectrum at 26°C, nonspinning

knowledge of the components of the chemical shift tensors in the molecular frame defining the ordering matrix. On the other hand, dipolar coupling constants can be used to calculate the order parameters of liquid crystals without relying on parameters estimated from model compounds. With broadband proton decoupling, dipolar coupling constants (D) between ^{13}C and ^{15}N ,³⁸ between ^{13}C and ^{19}F ,³⁹ and between two ^{13}C nuclei⁴⁰ can often be determined directly from the ^{13}C spectra, because the pairwise splittings are expressed by

$$\Delta\nu = 2D + J \quad (5)$$

where J is the scalar coupling constant, the anisotropy of which is usually small compared with the value of D and can be neglected. On the other hand, except for perdeuterated compounds,⁴¹ it is less straightforward to determine ^{13}C – ^1H dipolar coupling constants from the ^{13}C spectra.

To discuss this, let us first consider the example of benzene dissolved in a liquid crystalline solvent. With broadband ^1H decoupling, there is only a single sharp ^{13}C peak for benzene. On the other hand, the proton-coupled ^{13}C spectrum is complicated [Figure 2(a)] because the ^{13}C nucleus is coupled to six protons, which are in turn strongly coupled to each other. Although the spectrum can be analyzed exactly by

Figure 2 Carbon-13 NMR spectra of benzene dissolved in the liquid crystalline solvent ZLI 1167 at 75.43 MHz and 25°C. (a) Experimental spectrum without decoupling; the baseline is due to the solvent. (b) Calculated spectrum with complete ^1H – ^1H and ^1H – ^{13}C coupling. (c) Experimental spectrum with BLEW-48 decoupling and a decoupler power of 14 kHz. (d) Spectrum calculated by scaling the ^1H – ^{13}C coupling constants obtained from case (b) and setting the ^1H – ^1H dipolar coupling constants to zero

computer simulation [Figure 2(b)] due to the high symmetry of benzene, the spectral analyses for more complex molecules are practically intractable. This problem can be overcome by applying a special decoupling sequence to remove the ^1H – ^1H dipolar coupling, so that the ^{13}C spectrum becomes first order in terms of ^{13}C – ^1H coupling [Figure 2(c) and (d)].⁴² Among several well known dipolar decoupling sequences introduced for the study of solids, it was found that the so-called ‘BLEW-48’ sequence⁴³ is the most effective one for liquid crystal systems.⁴⁴ The first-order splittings resulting from using a dipolar decoupling sequence is given by⁴⁵

$$\Delta\nu = f[(3 \cos^2 \eta - 1)D + J] \quad (6)$$

where f is a scaling factor determined by the ^1H – ^1H dipolar decoupling sequence. For BLEW-48, the theoretical value is $f = 0.424$;⁴³ experimentally, the scaling factor varies slightly with the decoupler offset, and the best average value is $f = 0.420$.⁴² Although the sign of $\Delta\nu$ cannot be determined from the spectra, several different possibilities can be distinguished by a consideration of the molecular geometry and the macroscopic orientation of the liquid crystal in the magnetic field. Thus, for the spectrum shown in Figure 2(c), the values of $\Delta\nu$ for the directly bonded and the *ortho* C–H pairs can be measured directly from the first-order splittings

without computer simulation, and the corresponding values of D can be easily calculated by the use of equation (6). These values are the same as those obtained from a computer simulation of the spectrum [Figure 2(d)] within experimental error. This method is particularly useful for compounds with more complex structures, for which the completely coupled ^{13}C spectra are practically intractable by computer simulation.

For the ^{13}C spectra of bulk liquid crystals, there are many peaks in the spectra, and the ^{13}C – ^1H splittings overlap with each other. To resolve the splitting pattern of each ^{13}C peak unambiguously, a two-dimensional (2D) method called separated local field (SLF) spectroscopy^{46–49} can be applied. Like the MAS technique, the SLF method was first developed for solid state NMR. In this 2D method, the spin system is allowed to evolve with ^{13}C – ^1H coupling and ^1H – ^1H dipolar decoupling in the evolution period, so that information on dipolar coupling constants can be obtained from the ω_1 dimension. In the acquisition period, complete proton decoupling is applied, so that resolved peaks for individual carbon atoms can be obtained from the ω_2 dimension. Thus, ‘slices’ of the 2D spectra give clear splitting patterns for each chemically distinct ^{13}C peak, in the same way as the ‘heteronuclear 2D J -resolved’ method (see *Two-Dimensional J-Resolved Spectroscopy*).

The first application of the SLF method to liquid crystals was the study of EBBA with the director aligned along the magnetic field.³⁸ However, because of the presence of large ^1H – ^1H dipolar couplings which were not completely removed, the ^{13}C peaks in the ω_2 dimension were rather broad, and the splittings in the ω_1 dimension did not yield accurate ^{13}C – ^1H dipolar coupling constants. Later on, the application of the SLF method to study a static sample of an SmC* liquid crystal was also reported,⁵⁰ and a similar problem was encountered. In principle, increasing the decoupling power would alleviate this problem. However, it would create excessive rf heating and a large temperature gradient, which is not acceptable for liquid crystals.²²

5 STUDY OF ^{13}C – ^1H DIPOLAR COUPLINGS WITH VAS

Because the use of VAS can reduce dipolar couplings by a factor of $(3 \cos^2 \eta - 1)/2$ [equation (2)] or $-(3 \cos^2 \eta - 1)/4$ [equation (3)], a combination of VAS with the SLF method solves the problem of incomplete proton dipolar decoupling. For example, $(3 \cos^2 \eta - 1)/2 = 0.2$ for $\eta = 46.91^\circ$, and a nominal decoupler power (20–25 kHz) is sufficient to obtain good ^1H – ^1H dipolar decoupling with the use of the BLEW-48 sequence. It was shown that, for the application of the SLF method to EBBA, the use of VAS⁵¹ yielded much better first-order spectra in the ω_1 dimension than the use of a static sample.³⁸

As an example of the ^{13}C spectra obtained from the VAS/SLF technique, the spectra of 4-*n*-heptyl-4'-cyanobiphenyl (7CB) at 75 MHz and 31°C are shown in Figure 3.⁵² It can be seen that all seven peaks in the aliphatic chain and all nine peaks in the mesogenic core are resolved in the ω_2 dimension. The spectra in the ω_1 dimension show first-order ^{13}C – ^1H splittings. The CH_3 group exhibits a clear quartet, and each of the CH_2 groups exhibits a triplet, with discernible

Figure 3 2D ^{13}C NMR spectra of 7CB at 75.43 MHz and 31°C obtained by the SLF/VAS method. The spectra were obtained with variable angle spinning at $\eta = 45.6^\circ$. The spectra in the ω_1 dimension are shown on the left, and the first spectrum in the ω_2 dimension is shown on the right. long range splittings for the α - and β -carbons. Each peak for the quaternary carbons (1, 4, 1', and 4') in the phenyl rings is split into a triplet by the *ortho* protons, and each peak for the protonated carbons (2, 3, 2', and 3') is split into a doublet of doublets by the directly bonded and the *ortho* protons, respectively. Some of the peaks overlap slightly, but the values of $\Delta\nu$ can be readily obtained by least-squares analysis of the spectra. Then, the ^{13}C - ^1H dipolar coupling constants can be evaluated by the use of equation (6), and the order parameters for the corresponding molecular segments can be calculated. The procedure for the calculation is briefly summarized in the following discussion.

In the nematic phase, each phenyl ring has an effective D_2 symmetry because it undergoes rapid jumps between four equilibrium positions. Therefore, two order parameters, S_{zz} and $S_{xx} - S_{yy}$, are sufficient to describe the orientational ordering of each ring. These order parameters are related to the dipolar coupling constant of each C-H pair in the ring by

$$D_{ij} = -\frac{\gamma_i \gamma_j h}{8\pi^2 r_{ij}^3} [(3 \cos^2 \theta_{ijz} - 1) S_{zz} + (\cos^2 \theta_{ijx} - \cos^2 \theta_{ijy}) \times (S_{xx} - S_{yy})] \quad (7)$$

where r_{ij} is the internuclear distance and $\theta_{ij\alpha}$ is the angle between r_{ij} and the molecular axis α . The twofold axis of the phenyl ring is taken as the z axis, and the axis perpendicular to the plane of the phenyl ring is taken as the y axis. Assuming that $r_{\text{CC}} = 0.140$ nm and $r_{\text{CH}} = 0.108$ nm, the order parameters

and the bond angles can be calculated from least-squares fitting of a set of D values to equation (7). This procedure has been used to determine the order parameters of the phenyl rings in many liquid crystals.^{45,52-67}

The situation is more complicated for phenyl rings with lateral substituents or compounds containing cyclohexyl rings, and more order parameters are needed to describe the orientational ordering of the rings. The cyclohexyl ring in a liquid crystal has a C_s symmetry, and an additional order parameter S_{xy} is needed to describe the orientational ordering of the ring. Unfortunately, the ^{13}C peaks in the ω_1 dimension are quite broad due to unresolved long range couplings.^{55,56,66} Therefore, only approximate values of S_{zz} and $S_{xx} - S_{yy}$ were obtained by assuming $S_{xy} \approx 0$. A laterally substituted phenyl ring or a substituted cyclohexyl ring has no symmetry, and all five order parameters are nonzero.

The aliphatic chain has a large number of segmental motions, and it is difficult to define the order parameters for the whole chain. A simplified treatment can be made to define a C-H bond order parameter for each aliphatic segment, considering the C-H bond as having an approximate axial symmetry. Then, the order parameter for the C-H bond is related to the corresponding C-H dipolar coupling constant by

$$D = -\frac{\gamma_C \gamma_H h}{4\pi^2 r_{\text{CH}}^3} S_{\text{CH}} \quad (8)$$

in which the value of r_{CH} is generally assumed to be 0.110 nm.

The results for studying the orientational ordering of 5CB using the VAS/SLF technique have been compared with those obtained from deuterium NMR.⁴⁵ A good agreement was obtained, establishing the validity of the VAS/SLF method. This method has been further applied to investigate the orientational ordering of a large number of liquid crystals, including 4-*n*-alkyl-4'-cyanobiphenyls (*k*CBs, where *k* is the number of carbon atoms in the alkyl chain),^{45,53,59,60} 4-*n*-alkoxy-4'-cyanobiphenyls (*k*O CBs),⁵⁴ phenylcyclohexanes,^{52,55,56} bicyclohexylnitriles,⁶⁶ ferroelectric liquid crystals of the α -chloroesters of 4-alkoxy-4'-hydroxybiphenyls^{57,61} and of 4'-hydroxyphenyl-4-alkoxythiobenzoates,⁵⁸ 4'-cyanophenyl-4-alkylcarboxylates,⁶² 4-*n*-alkoxybenzylidene-4'-*n*-alkylanilines (*n*O.ms),⁶³ nematic compounds with four-unit links between two phenyl rings,^{64,65} and liquid crystals with lateral substituents.⁶⁷

6 APPLICATIONS COMBINING MEASUREMENTS OF CHEMICAL SHIFTS AND DIPOLAR COUPLINGS

It was mentioned in the Introduction that the use of equation (1) to determine the order parameters from anisotropic ^{13}C chemical shifts requires the knowledge of the components of the chemical shifts tensors in the axis system defining the ordering matrix. To avoid this difficulty but still take advantage of the simplicity and accuracy in the chemical shift measurement, an empirical approach has been suggested.⁶⁰ The method involves a determination of the order parameters of a liquid crystal at several temperatures by using the VAS/SLF technique as described in the previous section, and

a measurement of the ^{13}C chemical shifts for the same sample with slow spinning at $\eta = 0^\circ$. The order parameter S_{zz} for the phenyl rings or S_{CH} for the aliphatic chains is plotted against the corresponding ^{13}C chemical shifts, and it has been found that they are linearly related:

$$\delta^{\text{obs}} - \delta^{\text{iso}} = aS + b \quad (9)$$

where a and b are constants.⁶⁰ Although equation (9) is a result of equation (1), it is only an empirical relationship for the following reasons. A strict theoretical correspondence between the two equations implies that $a = 2[\sigma_{zz} - (\sigma_{xx} + \sigma_{yy})/2]/3$ and that the other order parameters are independent of temperature. The first condition requires the major axis of the chemical shift tensor to coincide with the z axis of the ring or the C–H axis in the chain. Although this is approximately true for the carbon atoms lying on the z axis of the phenyl rings, it is not necessarily so for other carbon atoms. Usually the second condition is approximately fulfilled because the values of $S_{xx} - S_{yy}$ are very small and vary randomly with temperature within experimental error, and S_{xy} , S_{xz} , and S_{yz} are zero for phenyl rings without lateral substituents. These approximations make equation (9) a semiempirical relationship; nevertheless, it has been found to work surprisingly well for many types of compounds.^{60,62–65,67}

After the constants a and b in equation (9) have been determined from the experimental VAS/SLF data at several temperatures, the order parameter S at other temperatures can be calculated from the ^{13}C chemical shifts without the use of approximate values of the shift tensors estimated from model compounds. This method has several advantages. First, the chemical shifts can be obtained from 1D experiments, which require much less spectrometer and processing time than the 2D VAS/SLF method. Second, the chemical shifts can be determined more accurately than the dipolar coupling constants, and their systematic changes with temperature are less subjected to random experimental uncertainties. Third, investigators who do not have the VAS/SLF facility can obtain order parameters directly from ^{13}C chemical shifts using published values of a and b for other homologous compounds. Thus, although the order parameters determined from ^{13}C chemical shifts via the use of equation (9) is an indirect method, the study of their temperature dependence is greatly facilitated. Problems such as the effect of various solutes on the orientational ordering of liquid crystal solvents,⁵⁴ the order of phase transitions,⁶³ and the temperature dependence of the position of the major axis of the mesogenic core^{64,65} can be studied more conveniently by this method.

7 RELAXATION

Because of the presence of orientational ordering, the translational and rotational motions of liquid crystals are highly anisotropic. As a result, their relaxation behavior is very different from that of isotropic liquids. Details of relaxation in liquid crystals are discussed in the articles by Hoatson (see *Deuteron Relaxation Rates in Liquid Crystalline Samples: Experimental Methods*) and Nordio (see *Liquid Crystalline Samples: Relaxation Mechanisms*). Examples of the study of ^{13}C relaxation are summarized below.

The earliest ^{13}C spin–lattice relaxation time (T_1) measurements reported were for 4,4'-azoxyanisole^{68,69} and MBBA.⁷⁰ More recently, a comprehensive investigation of ^{13}C T_1 and nuclear Overhauser enhancement (NOE) of 4- n -alkyl-4'-cyanobiphenyls ($k\text{CBs}$; $k = 5, 6, 7$, and 8) as functions of temperature and at different resonance frequencies has been made by Lewis, Tomchuk, and co-workers.^{71–73} They analyzed the results by considering angular fluctuations as well as director fluctuations, and concluded that at high fields the contribution of ^{13}C chemical shift anisotropy to relaxation is important, but cautioned that the quantitative analysis is not straightforward.

A better understanding of the dynamic behavior of liquid crystals can be obtained by investigating the relaxation of several kinds of nuclei in the same molecule. A small probe molecule, CH_3CN with ^{13}C enrichment, was used for such study by two groups of investigators.^{74–78} Grant and co-workers measured the relaxation of ^1H and ^{13}C with non-, semi-, and completely selective excitation of individual spectral lines.^{76,77} Later on, Luyten et al. carried out similar measurements, plus ^{14}N relaxation, at six different field strengths, and calculated the contributions of rotational anisotropy, random local field, and director fluctuation to the relaxation process.⁷⁸

Multinuclei relaxation measurements including ^{13}C and other nuclei have also been made for lyotropic liquid crystal systems,⁷⁹ phospholipids,^{29–31} and lead carboxylates.⁸⁰ The ^{13}C relaxation of an SmC^* compound has been reported recently.¹⁸

8 CONCLUSIONS

In applying ^{13}C NMR to study liquid crystals, the major parameters of interest are anisotropic chemical shifts, ^{13}C – ^1H dipolar coupling constants, and ^{13}C relaxation times. The advantages of ^{13}C NMR are its high resolution with regard to the chemical structure of the liquid crystal molecules, and the use of naturally abundant compounds without the need for special isotope substitution. However, macroscopic sample orientation is required to obtain resolvable ^{13}C peaks unless MAS is used. Therefore, ^{13}C NMR is not very informative for the study of unaligned samples generally found for higher smectic phases, discotic phases, and liquid crystal polymers. Furthermore, ^{13}C relaxation measurements do not offer as much information on relaxation mechanisms as ^2H relaxation measurements. Therefore, ^{13}C NMR and ^2H NMR complement each other, and both offer more detailed information than ^1H NMR in the study of liquid crystals.

1 INTRODUCTION

NMR spectra of small molecules dissolved in organic liquid crystalline media permit measurement of large numbers of intramolecular dipolar couplings that carry very precise information on molecular structure.^{1,2} However, for molecules with more than half a dozen protons, the strong degree of solute alignment obtained in such media typically results in a vast number of large, non-first-order splittings that make these spectra difficult to analyze. On the other hand, very weak alignment, caused by a molecule's own magnetic susceptibility anisotropy, also gives rise to measurable dipolar couplings.^{3,4} However, typically only the largest couplings are detectable and manifest themselves as small, field-dependent changes in the corresponding J splittings. The advantages of such ultra-weak alignment are that the NMR spectrum retains its regular high-resolution simplicity and that, owing to the extremely weak magnetic forces involved, it does not perturb the structure of the molecule.

Tolman et al.⁵ demonstrated that small dipolar couplings, on the order of a few hertz, could be measured for the backbone amides in paramagnetic myoglobin, and that these data correlate well with values expected on the basis of its crystal structure. Tjandra et al. subsequently measured a substantial number of very small ^{15}N – ^1H and ^{13}C – ^1H dipolar couplings in a diamagnetic protein-DNA complex and demonstrated that incorporation of these data as restraints in the structure calculation yields a remarkable improvement in both local and global geometry.⁶ In particular, by defining the relative orientation of structural elements in a macromolecule

with few interconnecting NOEs, these dipolar restraints solve a long-standing problem.

General applicability of the weak alignment approach greatly increased when the suitability of very dilute liquid crystalline media for this purpose was discovered.^{7–14} The macromolecules are dispersed in the aqueous phase that separates the highly ordered liquid crystalline particles, which have a spacing much larger than the diameter of the molecule under study. Despite the typically rather large macroscopic viscosity of such samples, the ordered particles are spaced by essentially pure water, and usually no adverse effect on rotational diffusion is therefore observed.⁷ However, exceptions to this rule can occur in cases where alignment is dominated by attractive electrostatic interactions between the nematogen and the solute.¹⁵ As discussed in Section 4.6, an alternate way for inducing weak alignment relies on axially compressed or stretched polyacrylamide gels. From a theoretical perspective, alignment in gels and in dilute lyotropic liquid crystalline suspensions are very similar.

The ability to tune the degree of macromolecular alignment over more than an order of magnitude, usually in the range from 3×10^{-4} to 3×10^{-3} , makes it possible to measure a whole plethora of short-range dipolar interactions, including those between directly bonded ^1H – ^{13}C , ^1H – ^{15}N , ^{13}C – ^{13}C and ^{13}C – ^{15}N pairs, and also between spatially proximate non-bonded ^1H – ^1H , ^1H – ^{13}C and ^1H – ^{15}N spin pairs.^{8,16–18} The measurement and application of dipolar couplings and CSA effects in weakly oriented macromolecules has already proven to be extremely useful in biomolecular structural studies. Several reviews have appeared on various aspects of this work,^{19–22} and further developments in this area of research are occurring at a very rapid pace. Even at present, a comprehensive review of this area would fill hundreds of pages, and is therefore well beyond the scope of this article. Instead, the relation between this work and conventional liquid crystal NMR will be highlighted, as well as illustrating some of the advantageous features of the weak ordering approach.

2 THEORETICAL CONSIDERATIONS

Although standard theory described for liquid crystals elsewhere in this encyclopedia is directly applicable to the case of very weakly ordered macromolecules, the early applications of the weak ordering technology derive from the magnetic-susceptibility induced alignment. As a result, the terminology differs somewhat and will be briefly reviewed below.

2.1 Dipolar Couplings in Aligned Macromolecules

The relation between the internuclear vector and the dipolar coupling between two spins, A and B can be found in numerous textbooks. For the purpose of deriving the resonance frequencies (i.e., dipolar splittings) only the z component of the local field of one nuclear dipole at the position of the second nucleus is relevant (secular approximation):

$$H_{dd} = D_{\max}^{AB} \langle I_{Az} I_{Bz} (3 \cos^2 \zeta - 1) \rangle \quad (1a)$$

where the $\langle \rangle$ brackets refer to the time or ensemble average, which are equivalent for isotropic and liquid crystalline

solutions, ζ is the angle between the $A - B$ internuclear vector and the magnetic field, and

$$D_{\max}^{AB} = \frac{-\mu_o(H/2\pi)\gamma_A\gamma_B}{(4\pi^2 r_{AB}^3)} \quad (1b)$$

is the static dipolar coupling in SI units (21.7 kHz for H–N pairs, assuming an internuclear distance $r_{NH} = 1.04 \text{ \AA}$). The constant, $-\mu_o$, is the magnetic permittivity of vacuum, h is Planck's constant, γ_X is the magnetogyric ratio of spin X , and r_{AB} is the distance between nuclei A and B . The residual dipolar splitting between spins A and B equals

$$D^{AB} = D_{\max}^{AB} \langle P_2(\cos \zeta) \rangle \quad (1c)$$

with $P_2(x) = (3x^2 - 1)/2$. Note that some texts differ in the definition of the dipolar coupling, D_{AB} , by a factor two.

If the molecule is rigid, the orientation of the internuclear vector, r_{AB} , in an arbitrary molecular coordinate system can be described by the angles α_x , α_y , and α_z between the vector and the x , y , and z axis of the coordinate system. The $P_2(\cos \zeta)$ term can be expressed as

$$\langle P_2(\cos \zeta) \rangle = \sum_{i,j=\{x,y,z\}} S_{ij} \cos \alpha_i \cos \alpha_j \quad (2)$$

where S is a traceless symmetric 3×3 matrix, commonly referred to as the Saupe matrix, the Saupe order matrix, or simply the order matrix.

If the structure of the molecule is known, i.e., $\cos \alpha_i$ factors in equation (2) are known, the five independent elements of S generally can be solved provided that dipolar couplings for at least five internuclear vectors are available. However, if any pair of internuclear vectors is parallel, and for other special cases such as a set that includes three mutually orthogonal interactions, more measured couplings are required. For macromolecules, many more dipolar couplings are frequently measured, and S is overdetermined. The Saupe matrix elements are then best determined using singular value decomposition.²³

The order matrix is real and symmetric, and it therefore is always possible to define a molecular axis system where S becomes diagonal. In a number of applications it can be advantageous to work in this principal axis frame, where D^{AB} now can be expressed in terms of the polar coordinates of the $A - B$ internuclear vector:

$$D^{AB}(\theta, \phi) = \frac{3}{2} D_{\max}^{AB} [\cos^2 \theta A_{zz} + \sin^2 \theta \cos^2 \phi A_{xx} + \sin^2 \theta \sin^2 \phi A_{yy}] \quad (3a)$$

where A is the diagonalized alignment tensor, with $|A_{zz}| > |A_{yy}| > |A_{xx}|$. This frequently is rewritten as

$$D^{AB}(\theta, \phi) = D_{\max}^{AB} \left[P_2(\cos \theta) A_a + \frac{3}{4} A_r \sin^2 \theta \cos 2\phi \right] \quad (3b)$$

where $A_a = 3A_{zz}/2$ is the axial component of the alignment tensor, and $A_r = (A_{xx} - A_{yy})$ is referred to as its rhombic component.

Note that the maximum value for A_a equals one when the z axis of the principal alignment tensor is fully aligned

with the static field. In practice, the dilute liquid crystal work discussed in this article concerns A_a values on the order of 10^{-3} . Equation (3b) is sometimes rewritten as

$$D^{AB}(\theta, \phi) = D_a^{AB} \left[(3 \cos^2 \theta - 1) + \frac{3}{2} R \sin^2 \theta \cos 2\phi \right] \quad (3c)$$

where $D_a^{AB} = 1/2 A_a D_{\max}^{AB}$ is referred to as the magnitude of the dipolar coupling tensor, frequently normalized to the N–H dipolar interaction, and $R = A_r/A_a$ is the rhombicity. Note that $0 \leq R \leq 2/3$.

2.2 Estimate for Alignment Tensor in Case of Unknown Structure

When working with a molecule of unknown structure, the above-described singular value decomposition approach for determining the order matrix is not applicable. However, as briefly discussed below, a reasonable estimate for the principal components of the alignment tensor can be obtained from the range and distribution of observed dipolar couplings.

First, it is convenient to normalize all observed one-bond and two-bond dipolar couplings to, for example, the N–H dipolar coupling, by multiplying the observed $P - Q$ dipolar coupling by $(\gamma_N \gamma_H r_{PQ}^3) / (\gamma_P \gamma_Q r_{NH}^3)$. Empirically determined optimum scaling factors are listed in Table 1. In the absence of measurement error in the dipolar couplings, the bond vector with the largest absolute value for the normalized dipolar coupling provides a lower limit for $2D_a^{NH}$ in equation (3c). Similarly, an estimate for the rhombicity R in equation (3c) can be obtained from the dipolar coupling value, D_{opposite} , with the other extreme value (negative for $D_a^{NH} > 0$; positive for $D_a^{NH} < 0$). The value of R itself, defined in this manner, is always positive and follows from $D_{\text{opposite}} = -D_a^{NH} [1 + 3/2R]$, or

$$R = -\frac{2}{3} \left[1 + \left(\frac{D_{\text{opposite}}}{D_a^{NH}} \right) \right] \quad (4)$$

This approach only uses the extreme values of the distribution of observed dipolar couplings. A more robust approach plots the histogram of the entire ensemble of normalized dipolar couplings.²⁴ Figure 1 shows an example of such histograms for the two globular domains of Ca^{2+} -ligated calmodulin. The histograms have been compiled from nearly complete sets of $^1D_{NH}$, $^1D_{C\alpha H\alpha}$, $^1D_{C'N}$, $^2D_{C'H\alpha}$ and $^1D_{C'C\alpha}$ couplings, recorded in a medium of filamentous phage *Pfl*.

Table 1 Magnitude of dipolar couplings relative to $^1D_{NH}$

	NMR ^a	X-ray ^b
$^1D_{C\alpha H\alpha}$	2.08	2.02
$^1D_{C\alpha C'}$	0.198	0.198
$^1D_{C'N}$	0.120	0.121
$^2D_{C'HN}$	0.300	0.319
$^1D_{CH3}$	0.628	0.628

^aValues that result in the lowest energy NMR structure of ubiquitin and yield best fit to $^{13}\text{C}'$ CSA.⁷⁴

^bOptimized by fitting experimental couplings to the ubiquitin X-ray structure.¹⁶

Figure 1 Histogram of normalized dipolar couplings measured in the N- and C-terminal domains of Ca^{2+} -ligated calmodulin, dissolved in a liquid crystalline medium containing 15 mg Pf1/ml and 10 mM KCl. Dipolar couplings are normalized relative to the one-bond ^{15}N - ^1H interaction. SVD fits to the crystal structure and the use of a freely floating alignment tensor during structure calculation⁷⁷ both yield $D_a^{\text{NH}} = 11.0 \text{ Hz}$; $R = 0.38$ and $D_a^{\text{NH}} = 10.1 \text{ Hz}$; $R = 0.66$ for the N- and C-terminal domains, respectively. Note that even while the two histograms cover the same width, they have considerably different asymmetries (rhombicity, R). A dearth of bond vectors parallel to the z-axis of the alignment tensor causes the absence of dipolar couplings $>22 \text{ Hz}$ for the N-terminal domain. Different types of dipolar couplings are shaded separately in the histograms: $^1D_{\text{NH}}$ – solid; $^1D_{\text{C}\alpha\text{H}\alpha}$ – shaded (///); $^1D_{\text{C}'\text{N}}$ – shaded (\\); $^1D_{\text{C}'\text{C}\alpha}$ – shaded (|||); $^2D_{\text{C}'\text{H}\alpha}$ – blank

It can be shown that for a uniform distribution of bond vectors, such a histogram will resemble the solid state powder pattern observed for chemical shift anisotropy.²⁵ In the present case, the singularities in the powder pattern correspond to D_{zz}^{NH} , D_{xx}^{NH} and D_{yy}^{NH} , with the condition that $D_{zz}^{\text{NH}} + D_{xx}^{\text{NH}} + D_{yy}^{\text{NH}} = 0$. The relation between the powder pattern singularities D_{zz}^{NH} , D_{xx}^{NH} , D_{yy}^{NH} and the parameters D_a^{NH} and R is given by:²⁴

$$D_{zz}^{\text{NH}} = 2D_a^{\text{NH}} \quad (5a)$$

$$D_{yy}^{\text{NH}} = -D_a^{\text{NH}}(1 + 1.5R) \quad (5b)$$

$$D_{xx}^{\text{NH}} = -D_a^{\text{NH}}(1 - 1.5R) \quad (5c)$$

If outliers appear to be present in the histogram, it is worth while checking the origin of these extreme dipolar couplings. They may correspond to $^1D_{\text{C}'\text{N}}$, $^2D_{\text{C}'\text{H}\alpha}$ or $^1D_{\text{C}'\text{C}\alpha}$ couplings derived from weak or partially overlapping correlations, and critical visual inspection of the raw data may be needed before including them.

3 MEASUREMENT OF DIPOLAR COUPLINGS

To date, measurement of dipolar couplings has focused primarily on one-bond interactions, which as a result of their known internuclear distance, are readily interpreted in terms of orientation. Also, they are generally the easiest to measure. Two-bond interactions also have the benefit of a fixed internuclear distance, but owing to their larger separation, they can be more difficult to measure at the same level of relative accuracy. New analysis schemes promise to make measurement of ^1H - ^1H dipolar couplings more straightforward, and they may also become popular as structural restraints.

Except for geminal ^1H - ^1H interactions and pairs of protons in structural elements of fixed geometry, the interproton distance is an additional parameter influencing the dipolar coupling. This therefore results in a less direct relation between the value of the coupling and the orientation of the corresponding vector. However, structure calculation programs such as CNS²⁶ can readily deal with this additional complexity.²⁷

So far, most measurements of dipolar couplings have focused on the one-bond and two-bond couplings along the polypeptide backbone in proteins (Figure 2), but dipolar couplings within and between sidechains are becoming increasingly used. Below, some of the most widely used techniques for measuring the various types of couplings are briefly discussed, with particular emphasis on ^{15}N - ^{13}C labeled proteins. With the exception of couplings between protons separated by more than three bonds, where the J coupling is usually negligible, the coupling observed in the liquid crystalline phase represents the sum of the scalar and dipolar contributions. Considerable variation in the scalar couplings frequently exists,

Figure 2 Protein backbone fragment, with dipolar interactions that can readily be measured marked by dashed lines. Although $D_{\text{NC}\alpha}$ can be measured experimentally, its relative accuracy tends to be lower, and for *trans*-peptide bonds its normalized value is very similar to that of $^1D_{\text{C}'\text{C}\alpha}$ of the preceding residue. $^1D_{\text{C}\alpha\text{C}\beta}$ is most useful in perdeuterated proteins, where no value for $^1D_{\text{C}\alpha\text{H}\alpha}$ can be measured and where the slow transverse relaxation of the deuterated $^{13}\text{C}\alpha$ permits its accurate measurement

making it necessary to measure the couplings both in the isotropic and aligned environment.

Two conceptually different approaches can be used for measurement of J or dipolar splittings. First, the splitting can be measured directly from a two- or three-dimensional spectrum recorded in the absence of decoupling of the interaction of interest. Frequently, an E.COSY,²⁸ S³E,²⁹ or IPAP version³⁰ of the multi-dimensional experiment is used in order to reduce overlap. Second, in a so-called quantitative- J correlation experiment,³¹ the size of the splitting can be derived from the intensity of a given resonance relative to that of a reference.

3.1 Accuracy of Measured Splitting

For splittings measured from relative peak displacements in the multi-dimensional NMR spectrum, the accuracy of a peak position is directly proportional to its signal-to-noise ratio, and inversely related to its line width. Although the accuracy also depends on the method used for peak position determination and on the digital resolution, a reasonable approximation for the root-mean-square uncertainty, ΔJ , in a measured splitting for a well resolved, undistorted, pure phase or pure antiphase doublet is given by:

$$\Delta J = \frac{LW}{SN} \quad (6)$$

where LW is the line width at half height (in the dimension where the splitting is being measured), and SN is the signal-to-noise ratio. Note that equation (6) provides a lower limit for the true accuracy of the measurement, because other distortions such as partial overlap or imperfect phasing can contribute to the error in a reproducible manner.

3.2 Measurement of $^1J_{\text{HN}}$

One-bond $^1D_{\text{NH}}$ dipolar coupling were the first ones to be measured in a weakly oriented protein, simply by recording a ^1H - ^{15}N HSQC spectrum without the regular ^1H 180° decoupling pulse applied at the midpoint of the t_1 evolution period. Transverse relaxation is considerably slower in the ^{15}N dimension compared to the ^1H dimension, and measurement in the indirect ^{15}N dimension is therefore preferred over measurement in the ^1H dimension. However, the spectral crowding doubles when HSQC spectra are recorded without decoupling, typically resulting in an unacceptable degree of resonance overlap.

A conceptually very simple method for measuring $^1J_{\text{NH}}$ separates the F_1 -coupled HSQC into two separate subspectra, containing only the upfield or downfield components of the F_1 ^{15}N - $\{^1\text{H}\}$ doublets. This is done by interleaving two experiments: one where the F_1 ^{15}N - $\{^1\text{H}\}$ doublets are in phase, and one where they are exactly antiphase. The sum of the antiphase and the in-phase spectra yields a spectrum containing only the downfield components, whereas the difference yields the upfield components (Figure 3). This approach is referred to as IPAP (for in-phase and anti-phase)³² and is easily extended to higher dimensionality experiments.

A small region of the two-dimensional ^1H - ^{15}N IPAP-HSQC spectrum of calmodulin is shown in Figure 3. Isotropic ^1H - ^{15}N J splittings are ca. 93 Hz, and the large deviations

Figure 3 Small region of the IPAP ^{15}N - ^1H HSQC spectrum of Ca^{2+} -ligated calmodulin in *Pfl* medium. The solid and dashed contours correspond to the downfield and upfield ^{15}N - $\{^1\text{H}\}$ doublet components, which are separated into two two-dimensional subspectra. These subspectra are superimposed in this plot for visual simplicity, as none of the resonances overlap one another in the displayed region of the spectrum. The size of the splittings are marked in the figure and correspond to $|^1J_{\text{NH}} + ^1D_{\text{NH}}|$

from this value correspond to the dipolar contributions to these splittings. So, both the sign and the magnitude of the dipolar coupling are obtained from such spectra.

3.3 Measurement of $^1J_{\text{C}'\text{C}\alpha}$

Due to the longer internuclear distance, and the lower product of the gyromagnetic ratios involved, the $^1D_{\text{C}'\text{C}\alpha}$ coupling is inherently five times smaller than the one-bond ^1H - ^{15}N coupling (Table 1). In order to obtain meaningful information, it therefore is necessary to measure this coupling at high accuracy. There are two ways to measure $^1J_{\text{C}'\text{C}\alpha}$: observation of the C' or of the C' resonance in the absence of decoupling the non-observed spin. For protonated proteins at moderate field strengths (≤ 14 T), the $\text{C}'T_2$ is invariably much longer than the $\text{C}^\alpha T_2$, favoring detection of C' for most accurate measurement of $^1J_{\text{C}'\text{C}\alpha}$. For perdeuterated proteins, detection of $^{13}\text{C}'$ in the presence of ^2H and $^{13}\text{C}^\beta$ decoupling yields narrower ^{13}C resonances, particularly at higher fields.

Usually, the most accurate method for measurement of $^1J_{\text{C}'\text{C}\alpha}$ is to simply record a 3D HNCO spectrum where the C^α pulse, normally applied at the midpoint of the $^{13}\text{C}'$ evolution period, is omitted.³³ The HNCO experiment yields among the best resolved triple resonance spectra and the two-fold increase in the number of resonances relative to the $^{13}\text{C}^\alpha$ -decoupled spectrum is generally not much of a problem. The $^{13}\text{C}'$ transverse relaxation rate is dominated by its chemical shift anisotropy, and $^{13}\text{C}'$ line widths at 600 MHz are about 30% larger than at 500 MHz ^1H frequency. It is therefore preferable to measure the $^1J_{\text{C}'\text{C}\alpha}$ splitting at a relatively low magnetic field strength.

3.4 Measurement of $^1J_{C'N}$ and $^2J_{CHN}$

Dipolar couplings across the peptide bond between $^{15}N_i$ and $^{13}C'_{i-1}$ are inherently 8.3 times weaker than $^1D_{NH}$ (Table 1). Therefore, accuracy of their measurement is critical for making optimal use of these small couplings in structure determination. Owing to the favorable relaxation properties of ^{15}N , especially when selecting the downfield ^{15}N - $\{^1H\}$ doublet component, the $^1J_{C'N}$ coupling is detected through the ^{15}N and not the $^{13}C'$ nucleus. The simplest method just records a two-dimensional HSQC on the $^{13}C/^{15}N$ doubly labeled protein, and inserts a $^{13}C^\alpha$ but not a $^{13}C'$ 180° decoupling pulse at the mid-point of ^{15}N evolution.³⁴ The resulting doublet in the ^{15}N dimension corresponds to $^1J_{C'N}$. Interestingly, the detected amide proton is also coupled to $^{13}C'$ (which has not changed its spin state during or after ^{15}N evolution). Therefore, the two doublet components are also displaced relative to one another by the $^2J_{CHN}$ coupling in the 1H dimension. Although normally this splitting would be very difficult to resolve because the $^1H^N$ line width is typically much larger than the $^2J_{CHN}$ coupling, the E.COSY principle²⁸ effectively separates the two $^1H^N$ - $\{^{13}C'\}$ doublet components (Figure 4).

An interesting alternative approach, based on the principle of quantitative J correlation, derives $^1J_{C'N}$ from the relative intensities of two interleaved 3D TROSY-HNCO spectra.³⁵ In one experiment (reference spectrum) the pulse scheme uses optimal one-bond ^{15}N - $\{^{13}C'\}$ dephasing of 33 ms, whereas in the second experiment (attenuated spectrum) the dephasing delay is set near the null condition (66 ms). Any deviation from $^1J_{C'N} + ^1D_{C'N} = (66 \text{ ms})^{-1}$ results in non-zero intensity in the second spectrum. The relative intensities of these two spectra then give a very precise measure for $^1J_{C'N}$, and permit

$^1D_{C'N}$ to be derived at an accuracy that is a fraction of a hertz, provided the signal to noise in the reference spectrum exceeds 20:1.

3.5 Measurement of $^1J_{C\alpha H\alpha}$ and $^1J_{C\alpha C\beta}$

Although, in principle, $^1J_{C\alpha H\alpha}$ can be measured from a 1H - ^{13}C two-dimensional correlation spectrum, recorded in the absence of heteronuclear decoupling in either the F_1 or F_2 dimension, the increase in spectral crowding frequently leads to unacceptable overlap for all but the smallest proteins. In practice, therefore, $^1J_{C\alpha H\alpha}$ is most commonly measured either from a series of J_{CH} -modulated HSQC spectra, simultaneous to measurement of sidechain J_{CH} couplings (see below), or from a H^α -coupled HN(CO)CA or (HA)CA(CO)NH spectrum. This latter experiment makes it easy to decouple the $^1J_{C\alpha C\beta}$ coupling by using a constant-time C^α evolution period, and is therefore preferred when dealing with small or medium-size proteins. Its pulse sequence is identical to a scheme previously used for measuring relaxation interference between the $^{13}C^\alpha$ CSA tensor and the $^{13}C^\alpha - ^1H^\alpha$ dipolar interaction,³⁶ but now it is the splitting itself rather than the difference in doublet intensities that is the focus of the measurement.

In perdeuterated proteins, $^1J_{C\alpha H\alpha}$ is inaccessible, but the long $^{13}C^\alpha$ transverse relaxation time permits measurement of $^1J_{C\alpha C\beta}$ from a regular HNCA experiment, recorded in the presence of 2H decoupling during $^{13}C^\alpha$ evolution.³⁷

3.6 Measurement of Sidechain $^1J_{CH}$ Couplings

To date, most attention has focused on measurement of backbone-related dipolar couplings. Nevertheless, dipolar couplings also are starting to become used for studying sidechain conformations. However, a significant fraction of the sidechains may be subject to rotameric averaging, which reduces the dipolar coupling relative to a static, single conformation. If the smaller dipolar coupling is imposed during structure calculation as if it were rigid, this can result in distorted sidechain conformations with high energy. A way around this is to impose the observed dipolar coupling as a lower bound for the true dipolar coupling.³⁸ An even better way would be to evaluate for each site separately what the degree of sidechain mobility is by conducting the requisite relaxation experiments.

For small and medium-size proteins, an accurate way for extracting both backbone $^1J_{C\alpha H\alpha}$ and sidechain $^1J_{CH}$ couplings is the recording of a set of CT-HSQC spectra, in which the 1H 180° decoupling pulse is systematically shifted. The intensity modulation pattern observed in the fully decoupled CT-HSQC spectrum then provides an accurate measure for $^1J_{CH}$. For methylene groups, the modulation frequency corresponds to the sum of the two $^1J_{CH}$ couplings. Methyl group intensities are modulated by $^1J_{CH}$ and by $3 \times ^1J_{CH}$, with amplitudes of the modulation having a ratio of approximately 1:3. As a result of the rapid three-fold rotation about the three-fold symmetry axis of the methyl group, the $^1D_{CH}$ dipolar coupling is scaled down by -0.31 relative to its static value.³⁹ Figure 5 compares the $^1D_{CH}$ and $^1D_{CC}$ dipolar couplings for methyl groups in ubiquitin. The tight correlation seen in this figure testifies to the precision at which these dipolar couplings can be measured. As suggested by this figure, for structure calculation

Figure 4 Small region of the ^{15}N - 1H HSQC spectrum of the first immunoglobulin binding domain of protein G, recorded in the absence of $^{13}C'$ decoupling in *Pf1* liquid crystal (11 mg ml^{-1}). The vertical and horizontal displacements within each doublet correspond to $^1J_{C'N} + ^1D_{C'N}$ and $^2J_{CHN} + ^2D_{CHN}$, respectively. Doublets are labeled by their one-letter residue type and number

Figure 5 Plot of $^1D_{CH}$ versus $^1D_{CC}$ residual dipolar couplings of methyl groups in the protein ubiquitin, dissolved in a liquid crystalline medium containing 5% (w/v) bicelles. The solid line represents the best fit of the data by linear regression, with a slope of -3.17 ± 0.03 . The outlier, labeled A46, corresponds to an alanine residue with a positive ϕ angle, for which there is a steric clash between the methyl group and a backbone carbonyl oxygen. (Reprinted, with permission, from Ottiger et al.³⁹)

purposes the methyl group $^1D_{CH}$ value may be converted into $^1D_{CC}$, thereby restraining the C–C(H₃) orientation.

For larger proteins, the lower sensitivity and increased spectral overlap in a CT-HSQC spectrum frequently result in a relatively small fraction of residues for which the $^1J_{CH}$ coupling can be measured. As an alternative, spectra recorded with CCH-COSY or HCCH-COSY, without decoupling in the detected dimension may be used for measurement of J_{CH} . An additional benefit of this approach is that for the case of non-equivalent methylene protons, both J_{CH} couplings can be measured separately. In favorable cases, the 1H – 1H multiplet structure in such spectra also permits measurement of $^2J_{HH}$.⁴⁰

3.7 Measurement of 1H – 1H Couplings

The history of measuring 1H – 1H J couplings is particularly rich and has been reviewed in numerous places. The E.COSY approach, applied in either a homo- or heteronuclear manner has proven particularly useful in this respect.²⁸ However, few of these methods are suitable for measurement of 1H – 1H dipolar couplings. When oriented, 1H – 1H multiplet structure tends to become very complex as a result of the multitude of coupling partners any given proton experiences. Fortunately, in heteronuclear type E.COSY spectra this does not pose a serious problem, and the utility of triple resonance experiments for measurement of both the sign and magnitude of intraresidue and sequential $J_{H\alpha HN}$ couplings has been demonstrated in oriented media.⁴¹ Nevertheless, with some exceptions,^{42,43} such experiments tend to be less suitable for measurement of dipolar couplings that are spatially proximate but far apart in the covalent bond network. Alternatively, the popular HNHA experiment can be used for measuring 1H – 1H dipolar couplings that involve an amide proton.^{6,44} In this experiment, the magnitude of $|J_{HH} + D_{HH}|$ is derived from the diagonal to cross peak intensity ratio. So, except for the intraresidue

H^N – H^α interaction, where there also is a significant scalar contribution to the interaction, the sign of D_{HH} is not available from this experiment.

4 ALIGNMENT MEDIA FOR MACROMOLECULES

A prerequisite for studying macromolecules in a liquid crystalline phase is that the order imposed on the macromolecule is very small, typically less than 0.002. The order of the liquid crystal particles themselves is invariably much higher, in the 0.5–0.85 range. Clearly, for achieving such a weak solute alignment in the strongly oriented liquid crystalline medium, interaction between the macromolecule and the liquid crystal must be very weak. The medium must also be aqueous, such that the proteins or nucleic acids remain in their natural environment. An efficient way to satisfy these conditions is the use of a very dilute ($\leq 10\%$ (w/v)) lyotropic nematic liquid crystalline suspension, where the nematogenic unit itself is a large particle. In a liquid crystalline phase, the weak steric and electrostatic interactions between liquid crystal particles cause their cooperative alignment. There is a lower limit for the nematogen concentration, c_n , required to form a stable liquid crystalline phase. If the sample is diluted below this threshold, it separates into an isotropic phase with concentration c_i and a nematic phase, with the c_n being 5–20% higher than c_i . The aspect ratio of the nematogenic particle is a critical determinant for the lowest concentration at which liquid crystalline ordering occurs. The time needed for formation of a homogeneous liquid crystalline phase strongly depends on the nematogen concentration, and can be very long for concentrated samples, but also for samples that are close to the threshold concentration, where separation between microscopic aligned and isotropic domains takes place.

All liquid crystalline media that have proven to be useful for weak ordering of proteins and nucleic acids consist of large ($> 1000 \text{ \AA}$), water-soluble particles, with relatively low surface charge densities ($\leq 0.5 e \text{ nm}^{-2}$). The interaction between the liquid crystal particles results in increased macroscopic viscosity relative to pure water. However, rotational diffusion of the macromolecule itself is virtually unchanged, unless it has a weak affinity for the liquid crystal particle. In the latter case, the degree of order typically is much too large and therefore is of little practical interest. For all lyotropic liquid crystals discussed below, the degree of order imposed on the solute can be adjusted by changing the concentration of the liquid crystal itself over the range where it yields an ordered phase. There is not yet a single, ideal liquid crystal. For example, phospholipases without inhibitors cannot be studied in bicelles as they break down the phospholipids; active proteases can destroy phage-based liquid crystals; other proteins may stick to phospholipids, or the surface charge distribution of the liquid crystal may cause too strong an electrostatic interaction with the solute. Also, liquid crystals require some degree of surface charge to keep their order and may fail to remain liquid crystalline at high salt concentrations. Below, several of the most widely used systems are briefly discussed.

4.1 Bicelles

Bicelles were the first liquid crystalline medium used for weak alignment of proteins and DNA.^{7,8} These are planar

bilayered particles that usually consist of regular saturated phospholipids. Most commonly, a mixture of dimyristoyl phosphatidyl choline (DMPC) and dihexanoyl phosphatidyl choline (DHPC) is used. DMPC makes up the bilayer, which constitutes the plane of the bicelle, and the DHPC detergent protects the long DMPC alkyl chains at the rims of the bilayer from exposure to solvent. Bicellar liquid crystals were originally developed by Prestegard, Sanders and co-workers for the purpose of studying lipophilic molecules, anchored in these highly ordered membranes.^{45,46} The DMPC/DHPC combination was found to be particularly robust. When raising the temperature above 25 °C, the system switches from isotropic to a nematic liquid crystalline phase.⁴⁷ This temperature corresponds to the melting temperature of DMPC, i.e., the temperature at which the saturated alkane chains of DMPC melt from a crystalline or gel state, in which the alkane chains are all *trans*, to a flexible, liquid crystalline phase. Near this transition temperature, the sample has high macroscopic viscosity and tends to be slightly opaque. Below 25 °C the solution remains clear and unordered and both small angle neutron scattering and NMR diffusion experiments indicate the bicelles to be disk-shaped bilayers in this unordered phase.^{48,49}

The phase diagram of the DMPC/DHPC mixture is very complex and depends on a large number of variables, including the absolute concentration, the molar ratio $[\text{DMPC}]/[\text{DHPC}] = q$, temperature, ionic strength, and on the presence of charged amphiphilic molecules such as sodium dodecyl sulfate (SDS) or cetyl trimethylammonium bromide (CTAB). Bicelles were long believed to remain disk-shaped above the DMPC melting temperature, with a diameter determined by q . However, the diameters predicted by such a model are incompatible with the very dilute concentrations (down to $\leq 2\%$ (v/v)) at which the sample remains liquid crystalline. Recent tracer diffusion obstruction and neutron scattering data indicate the liquid crystalline phase to consist of highly porous bilayers, presumably with the detergent covering the rims of the pores.^{49,50}

Intrinsically, DMPC/DHPC bicelles can form a liquid crystalline phase over the temperature range of 25–45 °C. However, near the lower end of this range (25–30 °C), dilute samples tend to be unstable and they frequently separate into an aligned and an isotropic phase. This can be prevented by addition of a small molar fraction (typically 1–3%, relative to DMPC) of charged amphiphiles, such as CTAB (positive) or SDS (negative).⁵¹ Alternatively, charged phospholipids such as dimyristoyl phosphatidylserine (negative), or dimyristoyl trimethylammonium propane (positive) can be used. Charging the bicelles in this manner helps prevent phase separation and widens the part of the phase diagram over which the liquid crystalline phase remains stable. The electrostatic potential repels and attracts oppositely charged groups on the solute, and generally causes a change in both the orientation and magnitude of the alignment tensor. This can be a highly beneficial side effect, as it permits measurement of dipolar couplings under multiple orientations of the protein (Figure 6).⁵² Usually, this change in orientation is approximately linear with charge. So, if more than two different samples are prepared in this manner, they simply yield alignment tensors that are linear combinations of one another.⁵³

Regular phospholipids are subject to acid- and base-catalyzed hydrolysis of the carboxyester linkage between the

Figure 6 Orientations of the Gln⁴⁰ N–H vector in ubiquitin compatible with the ¹⁵N–¹H one bond dipolar coupling measured in undoped bicelles (band A) and in positively charged bicelles (band B). Orientations are given in the coordinate frame of the X-ray structure of this protein. Heavy lines correspond to the measured dipolar couplings; thinner lines correspond to orientations if D_{NH} is increased or decreased by 1 Hz. The solid dot marks the orientation of the N–H vector when the protons are model-built into the crystal structure, assuming H^{N} is located on the line bisecting the $\text{C}'\text{--N--C}^{\alpha}$ angle. (Adapted, with permission, from Ramirez and Bax⁵²)

alkyl chain and the glycerol backbone. The rate of hydrolysis is minimal at pH 6.5, but rapidly increases once the pH differs by more than one unit from this value.⁵⁴ Use of ether lipids, where the carboxyester bond is replaced by an ether linker can prevent this hydrolysis and such samples can be stable over a very wide range of pH^{55,56} for periods of several years.

The temperature range over which the bicelles are liquid crystalline can be extended either by introducing a small fraction of mono-unsaturated DMPC, which lowers the melting temperature of the alkane chain,⁵⁴ or by using shorter alkane chains. Use of shorter alkane chain phospholipids, such as dilauroyl PC (12-C chains)⁵⁷ or ditridecanoyl PC (13-C chains)⁵⁵ lowers the transition temperature by about 12 and 6 °C, respectively, and increases the upper temperature limit as well. However, the macroscopic viscosity of these solutions below the transition temperature tends to be much higher than for DMPC/DHPC bicelles, such that preparation of the sample can be more cumbersome, particularly when using a microcell.

4.2 Filamentous Phage

Use of a liquid crystalline solution consisting of filamentous phages for aligning macromolecules was introduced in 1998.^{9,10,58} Clore et al. used a medium based on the filamentous phage *fd*, and also demonstrated the potential of tobacco mosaic virus (TMV). The Pardi group demonstrated the utility of the phage *Pfl*, which is similar to *fd*, but which at a contour length of ca. 2 μm is nearly twice as long. Both phages have a diameter of 6.5 nm, and are quite rigid, with a persistence length of ca. 1 μm . As a result of the high aspect ratios of these particles, solutions can remain liquid crystalline down to very low concentrations, as low as a

few mg ml^{-1} . Although it was suggested that liquid crystallinity is independent of ionic strength, we find this to be true only at higher phage concentrations,¹⁵ whereas at lower concentrations ($\sim 13 \text{ mg ml}^{-1}$ for *Pfl*) the degree of alignment becomes sensitive to ionic strength, and at very high salt concentrations the samples become isotropic. In contrast to *fd*, *Pfl* solutions tend to remain homogeneous when their concentration is lowered below the nematic threshold concentration, c_n . However, below this threshold, the degree of both phage and solute alignment becomes a function of the magnetic field strength, characteristic of a so-called paranematic phase.¹⁵

The negative surface charge (ca. $0.5 e \text{ nm}^{-2}$) is necessary to maintain a uniform suspension of these large particles. When lowering the pH below 6, partial protonation of the glutamate and aspartyl sidechains of the phage coat protein reduces the net charge of the virus particle and the phage precipitates. However, *fd* has been shown to be soluble and liquid crystalline when the pH is reduced further, to ca. 3.⁵⁹

As highlighted by Clore et al. for an immunoglobulin-binding domain of Streptococcal protein G, the alignment tensor in the phage medium can be very different from that in the bicelle medium.¹⁰ This is advantageous as it permits measurement of dipolar couplings relative to two independent axis systems, thereby resolving much of the degeneracy that occurs in interpreting a dipolar coupling in terms of two orientational variables, θ and ϕ in equation (3c). The phage particles are aligned with their long axis parallel to the magnetic field. Therefore, if the alignment of solute macromolecules were caused exclusively by steric interaction, the alignment tensor would be very similar to that in the bicelle medium. In practice, the alignment tensors in phage and bicelle media tend to be quite different as there usually are relatively strong electrostatic interactions between the phage and the solute (see also Section 5).

4.3 Alkyl-poly(ethylene glycol) Based Media

A lyotropic liquid crystal consisting of a mixture of alkyl-poly(ethylene glycol) and hexanol is another very useful medium for protein and nucleic acid alignment.¹⁴ Alkyl-poly(ethylene glycol) type compounds generally do not tend to bind to proteins, making this an attractive medium for a wide range of biological systems. In contrast to bicelles, the liquid crystal is not subject to hydrolysis and it can remain stable for years, provided the concentration of hexanol does not decrease as a result of slow evaporation. The medium remains liquid crystalline over a wide pH range and a considerable temperature range of $10\text{--}40^\circ\text{C}$, which is tunable by varying the type of alkyl-poly(ethylene glycol) and the chain length of the alcohol.¹⁴

The different alkyl-poly(ethylene glycol) compounds are referred to as C_mEn , where m is the number of carbons in the alkyl group, and n is the number of ethylene glycol units. Typically, a hexanol to C_{12}E_5 molar ratio of 0.96 (5 wt.% C_{12}E_5 in H_2O) is used yielding a particularly stable liquid crystal that is easy to prepare, but the medium is relatively tolerant to changes in the absolute and relative concentrations. C_{12}E_5 is commercially available at low cost. In many cases, the sample can simply be recovered from the liquid crystal by extensive dialysis.

4.4 Other Liquid Crystals

Ternary mixtures of cetylpyridinium chloride (CPCl) or bromide (CPBr), hexanol, and NaCl or NaBr in water can form stable liquid crystalline phases over a wide range of conditions. Prosser et al.¹¹ demonstrated that the CPCl version yielded alignment for the protein ubiquitin, and Barrientos et al.¹² described the use of the CPBr based medium. Remarkable differences were found between the CPBr and CPCl based liquid crystals, with CPBr being more suitable for low ionic strength measurements ($10\text{--}40 \text{ mM}$ NaBr) and the CPCl system requiring higher salt concentrations ($200\text{--}500 \text{ mM}$ NaCl).¹²

Dilute suspensions of natural cellulose fibers, derived either from wood pulp or from filter paper by careful sulfuric acid hydrolysis, also can form a liquid crystalline phase suitable for macromolecular ordering.⁶⁰ Although negatively charged, the net surface charge density is lower than for filamentous phage, making it a useful complement to the other media, mentioned above. However, the lower surface charge and the smaller aspect ratio relative to filamentous phage result in a higher minimal threshold concentration for liquid crystal formation.

A suspension of purple membrane (PM) fragments has also been shown suitable for inducing a weak degree of macromolecular order.^{53,61} These fragments consist primarily (75% (w/w)) of bacteriorhodopsin, an integral membrane protein with seven transmembrane helices. The PM fragments have an average diameter of about $1 \mu\text{m}$. This is sufficiently large that the total magnetic susceptibility anisotropy of such a particle causes it to align nearly 100% when placed in a strong magnetic field ($\geq 11 \text{ T}$), with the membrane plane orthogonal to the direction of the magnetic field.⁶² So, in contrast to the bicelle, phage and CPBr systems, PM does not need to form a liquid crystalline phase for obtaining alignment.

The strong net negative surface charge of PM causes very weak transient binding of solute proteins that carry clusters of positively charged groups on their surfaces, and thereby can result in net alignment.^{53,61} The electrostatic interactions are typically weak enough not to distort the structure of globular proteins. However, as is the case with all liquid crystal studies in this chapter, when studying flexible regions in a protein, care must be taken when interpreting the dipolar coupling data as the protein only transiently interacts with the liquid crystal. Interaction with the nematogen may be favored when the flexible region temporarily adopts a given shape, whereas other, non-binding conformations of the flexible region may not be sampled.

4.5 Polyacrylamide Gel

In order to prevent sedimentation, suspensions of large particles such as phages, bicelles, and cellulose require a repelling interaction, i.e., a net surface charge. These local electrostatic fields generally result in stronger solute alignment, which then may become too strong for facile dipolar coupling measurement. In other cases, solutes may cause the liquid crystal particles to aggregate and precipitate. For example, no stable liquid crystal has yet been described that is suitable for detergent-solubilized proteins. So, although the above mentioned liquid crystalline systems will cover the majority of systems of interest, there remain exceptions.

Recently, a very useful alternative method for inducing weak alignment has been developed that is known as strain-induced alignment in a gel (SAG).^{63,64} This method relies on anisotropically compressed polyacrylamide gel, which forms an extremely stable and inert aqueous matrix for solute proteins, and even permits their study under partially or fully denaturing conditions.⁶⁵ The gels may either be compressed or stretched in the axial direction,⁶⁴ with stretching generally yielding stronger alignment.⁶⁶ The robustness of such a medium makes it particularly useful for challenging applications such as detergent-solubilized systems.⁶⁶ The solutes may either be diffused into the gel, or they may be included in the medium before polymerization of the hydrogel is induced.

Compression of the gel can simply be achieved by first casting it in a narrow diameter (3–3.5 mm) cylinder. Then, after soaking in the solute of interest, it is transferred to a regular 4.2-mm inner diameter (ID) NMR sample tube, followed by axial compression by a susceptibility-matched plunger. Stretching can be achieved by radial compression, using a funnel-like device to squeeze a larger diameter gel (5–7 mm) into a regular 4.2-mm ID NMR sample tube.⁶⁶ Polyacrylamide gels appear to yield the most widely applicable method for inducing weak macromolecular alignment as the system is very inert and stable. Their principal disadvantage is a potential decrease in rotational diffusion rate of the solute, resulting in line broadening.^{64,67} This latter effect can be minimized by using gel concentrations as low as possible ($\leq 5\%$) combined with high degrees of stretching, and by using low cross-linking ratios ($\leq 1:40$).

4.6 Use of Multiple Alignment Media

As discussed in Section 5, solute alignment is defined by both steric and electrostatic interaction. So, by using nearly neutral liquid crystals, such as bicelles or the alkyl poly(ethylene-glycol) medium, and a charged medium such as phage or the cetyl-pyridinium based phase, a single molecule can be studied using two or more independent alignment tensors. As illustrated in Figure 6, this removes much of the degeneracy in the relation between dipolar coupling and internuclear vector orientation.⁵² A dipolar coupling measured in a given medium defines the internuclear vector to be on one of two oppositely oriented cones. The alignment tensor in a second medium will generally be oriented differently relative to the molecular frame and a dipolar coupling defines the same vector to be situated on a different cone. The true internuclear vector orientation then must be located on one of the intersections between the two sets of cones (Figure 6). In the general case of a non-axially symmetric (rhombic) alignment tensor there are up to eight intersections. If a third, independent alignment tensor can be obtained, this degeneracy may be reduced to two-fold. The true orientation and its inverse can never be distinguished from measurements on a single dipolar interaction, and two-fold degeneracy is therefore the best that can be achieved for a single vector.

Besides changing the liquid crystal medium, the alignment tensor may also be altered by subtly changing the protein. For example, when the pH is altered such that the surface charge distribution becomes different, this will affect the alignment tensor in the charged liquid crystalline media. Similarly, if

protein preparations are available with and without a His-tag tail, their alignment tensors will generally be different, although not necessarily by a large amount. Also, for a protein with a His-tag, a relatively small change in pH from 6 to 7.5 can significantly alter the alignment tensor.

If one-bond dipolar couplings are measured for a set of non-collinear interactions in a fragment of known secondary structure, such as an α -helix, there are four different ways to orient the fragment relative to the alignment tensor. Dipolar couplings measured in a second, independent medium, can lift this degeneracy, defining its orientation uniquely.⁶⁸

5 RELATION BETWEEN ALIGNMENT AND SHAPE

Tjandra et al. demonstrated that in a bicelle medium the principal axes of the molecular alignment tensor closely coincide with those of the rotational diffusion tensor.^{8,69} This shows that in this nearly neutral medium, alignment is defined by the solute's shape. As mentioned above, the alignment tensor can be modified by adding a net charge to the bicelles, by doping them with either CTAB (+) or SDS (–). This demonstrates that electrostatic interactions also play a role. In fact, for an oriented medium of strongly negatively charged, rod-shaped viral particles, or oriented PM fragments, electrostatic interactions usually dominate alignment of solute proteins.

A simple steric model has been proposed that quantitatively describes the relation between the solute's shape and its alignment in the type of lyotropic liquid crystals described in this article.⁷⁰ So far, it has only been demonstrated for the case of (nearly) neutral particles, such as bicelles, but preliminary results indicate that the method can be extended to account for the effect of charge.

In the so-called steric-obstruction model, the solute sample can be simulated as a collection of randomly oriented, uniformly distributed molecules, from which the fraction that sterically clashes with the ordered array of liquid crystal particles is removed. For example, for a lamellar phase such as bicelles or C₁₂E₅, a larger fraction of molecules oriented orthogonal to the bilayer will be obstructed than molecules parallel to the surface, resulting in net ordering of the remaining, non-obstructed molecules. For each non-obstructed molecule a Saupe order matrix is calculated, using equation (2). Averaging of the Saupe matrices for all non-obstructed proteins then yields the sterically predicted alignment tensor.⁷⁰ In an extension of this method that accounts also for the effect of electrostatics, different weighting factors are given to each of the non-obstructed solute molecules, depending on the Boltzmann factor calculated when taking the electrostatic potential into account (M. Zweckstetter, unpublished results).

Figure 7 shows the correlation between the ¹⁵N–¹H dipolar couplings measured for the Ig binding domain of Streptococcal protein G, and that predicted from its 1.0 Å crystal structure, using an alignment tensor that is not best-fitted to the data, but calculated on the basis of its shape.⁶⁹ When ignoring electrostatics, the predicted alignment tensors for bicelle and phage media are very similar. However, the experimentally observed dipolar couplings in the two media are very different and, as expected, good agreement is only observed for the bicelle medium (Figure 7). When electrostatic terms are included in the calculations for the phage medium, the

Figure 7 Correlations between experimental $^1D_{\text{NH}}$ values and values calculated from the shape-predicted alignment tensor of the third immunoglobulin binding domain of protein G in (a) 5% (w/v) bicelle medium, and (b) 28 mg ml $^{-1}$ *fd* medium. Dashed lines correspond to $y = x$. The poor correlation in (b) indicates that in phage medium the protein alignment is dominated by electrostatic interactions, which are ignored in the alignment tensor prediction, and not by steric interaction. (Adapted, with permission, from Zweckstetter and Bax¹⁵)

agreement becomes nearly as good as for the neutral bicelle medium. Note that in contrast to the results of an SVD fit, the data shown in Figure 7 do not include any adjustable parameters. So, the alignment tensor orientation and magnitude are calculated on the basis of the protein's shape, and

subsequently dipolar couplings are predicted on the basis of the orientation of the internuclear vector relative to this alignment tensor.

6 STRUCTURE VALIDATION

One particularly attractive feature of dipolar couplings is that they can be used in a very direct manner to evaluate the accuracy of any given structure: the more accurate the structure, the better the agreement is between experimental dipolar couplings and this structure. In order to evaluate this agreement, one first needs to determine the alignment tensor or Saupe matrix. As mentioned earlier, there are two conceptually different ways to do this. One can either predict the alignment on the basis of the molecule's shape and charge distribution, or one can determine the Saupe matrix elements of equation (2) simply by singular value decomposition. There are five independent elements in the Saupe matrix. If the number of experimentally measured independent (i.e., non-collinear) dipolar interactions is much larger than five, the SVD approach is preferred as it eliminates the effect of errors in the shape-predicted alignment tensor. Clearly, for effective validation it is necessary that the number of observables (dipolar couplings) is much larger than the number of variables in the SVD fit. If this condition is not met, corrections can be made for the significance of the correlation in terms of F statistics. For proteins, typically the number of observed dipolar couplings is much larger than five, and the goodness of the fit provides a direct measure for the accuracy of the structure.

Figure 8 shows a typical example of the correlation between measured dipolar couplings and those predicted by two structures of the C-terminal domain of Ca $^{2+}$ -calmodulin (after best fitting the Saupe matrix to the experimental couplings). The first correlation (Figure 8a) is calculated by using the 1.0-Å X-ray crystal structure of *Paramecium tetraurelia* calmodulin to fit the data measured for the highly homologous mammalian protein. It yields a Pearson's correlation coefficient, R^P , of 0.95. The second structure was calculated on the basis of N-H, C'-N, H $^{\alpha}$ -C $^{\alpha}$ and C'-C $^{\alpha}$ dipolar couplings, and the H $^{\alpha}$ -C' couplings are best-fit to this structure. Clearly, the NMR structure ($R^P = 0.98$) predicts the experimental H $^{\alpha}$ -C' couplings better than the X-ray structure, which is related to a slight rearrangement of relative helix orientations in solution relative to the crystalline state.⁷¹

When accurate experimental dipolar couplings are available, it is always advantageous to incorporate them into the structure calculation process. However, once this is done, they no longer are useful for validation purposes. A way around this is to compare the observed and predicted changes in chemical shift between isotropic and aligned samples for a type of nucleus with a well-defined chemical shift anisotropy. The first application of this idea was for the change in ^{15}N chemical shift with field strength in a small protein-DNA complex,⁷² caused by the anisotropy of the magnetic susceptibility of this complex. Although the changes were minute (≤ 5 ppb), a clear improvement in the correlation was observed upon incorporation of dipolar couplings in the structure calculation process. Subsequently, comparison of much larger $^{13}\text{C}'$ chemical shift changes between a protein in isotropic and aligned bicellar medium also showed an excellent correlation with structure.⁷³

Figure 8 Correlation between measured, normalized $^2D_{C'H\alpha}$ dipolar couplings and those predicted by the 1.0-Å X-ray crystal structure (a), and by the NMR structures of the C-terminal domain of Ca^{2+} -calmodulin, calculated without $^2D_{C'H\alpha}$ couplings (b). The slightly better fit to the NMR structure is caused by a small rearrangement of the relative helix orientations in solution relative to those observed in the crystalline state of this protein⁷¹

7 CONCLUDING REMARKS

The introduction of methods for generating tunable, very weak alignment of macromolecules makes it possible to measure the one-bond and other short range dipolar couplings with a remarkable degree of accuracy. Even while the splittings are reduced by about three orders of magnitude relative to their static values, the narrow line widths and relatively high signal-to-noise ratio in high resolution NMR more than compensate for the low degree of order. For example, one-bond ^{15}N - ^1H dipolar couplings typically can be measured with an accuracy of ca. 0.1 Hz, whereas their range covers up to 50 Hz. Even for the intrinsically much smaller interactions, such as the one-bond ^{15}N - $^{13}\text{C}'$ dipolar coupling, the error typically is smaller by up to two orders of magnitude relative to the range of couplings observed. Similarly, chemical shift effects can be measured at a relative accuracy that rivals that attainable in solid state NMR, but the problem of resonance overlap is much less severe because isotropic shifts in solution are more effective at dispersing NMR spectra. Experimental correlations between $^{13}\text{C}'$, ^{15}N , and $^1\text{H}^{\text{N}}$ CSA tensors and secondary structure in proteins could be clearly established from such data.⁷⁴

Dipolar couplings are not very sensitive to small amplitude oscillations about an average orientation. Conversely,

relatively small discrepancies between observed and predicted magnitudes of dipolar couplings require rather large amplitude angular fluctuations if this discrepancy is entirely attributed to dynamic effects.^{75,76} Nevertheless, because averaging of the observed dipolar interactions is sensitive to motions that cover the entire time scale from milliseconds to femtoseconds, it can potentially provide a powerful complement for the study of dynamic processes.

Measurement of tensorial interactions in macromolecules is a new and rapidly expanding area in structural biology. It offers numerous new opportunities, including rapid determination of backbone folds, rapid structure determination, refinement of conventional NMR structures, and the study of relative orientations of components in multi-molecular complexes. It is likely that a further marriage between conventional solid-state NMR techniques and the weak alignment approach may expand these areas even further.

1 INTRODUCTION

Smectic liquid crystals, in particular the chiral smectics, have dominated fundamental liquid crystal research for at least two decades while nematics still completely dominate applications. In fact, notwithstanding the great complexity of these materials as well as their mechanical fragility, they appear very promising for technological applications. Recently, the ferroelectric liquid crystals (FLC), which have been under active study since their discovery in 1975, have been complemented with antiferroelectric liquid crystals (AFLC) discovered by Chandani et al. in 1989, and with a few intermediate phases (smectic C_α^* and C_γ^*).

The mesogens giving rise to these phases are usually flexible molecules containing a chiral center; even though noticeable exceptions are present, for simplicity here we will refer to these molecules as formed by an achiral chain, a central aromatic core and a chain bearing the chiral center. In the smectic phases the molecules, which can be roughly thought of as exhibiting a rod-like shape, are arranged within layers, but, while in the smectic A (S_A) the preferred direction of the mesogen long axes (the director) is parallel to the layer normal, in the smectic C (S_C) it is tilted. In ferroelectric S_C phases (S_C^*) a spontaneous polarization is observed within each layer in a direction perpendicular to the plane formed by the tilt direction and the smectic layer normal due to the polarity of the molecules. The direction of the tilt and spontaneous polarization slowly precess as we move along the layer normal. As a result a helical structure is formed, with a pitch of the order of the wavelength of the visible light (see Figure 1a). In the antiferroelectric S_C phase (S_{CA}^*) the molecules are still tilted with respect to the smectic layer normal, but the direction of the tilt alternates, and therefore the in-plane spontaneous polarization reverses by 180° , when moving from one smectic layer to the next (see Figure 1b). The structure of the C_α and C_γ phases is less certain at the molecular level although there

is a number of experimental and theoretical investigations. An hypothesis has been formulated that the smectic C_α phase is a sort of S_C^* with a much shorter helix pitch (see Figure 1c), while the ferroelectric C_γ shows two interdigitated helices as in the S_{CA}^* , but here the molecules are rotated by an angle different to 180° with respect to the helix axis when we move from one smectic layer to the next (see Figure 1d).

Over the past two years, interest in smectic liquid crystals has experienced a renaissance with active research in both the materials and their large-scale applications. Several reasons have contributed to this, in addition to the interest in AFLC and in the other S_C subphases. First of all, the mechanical fragility problem has been overcome by means of several solutions, moreover there has been the advent of FLC polymers, elastomers and polymer-reinforced FLC materials. These reasons, together with a high improvement in addressing technology, make FLCs good candidates for the next generation of Liquid Crystal Displays. However, at this moment, the molecular mechanism behind these materials, as well as their physics, and in particular the conditions responsible for the occurrence of ferroelectric and antiferroelectric phases, are still under investigation.¹ The structural behavior and, sometimes even the identification of existing subphases has not yet been performed and this is an important task which could be undertaken by spectroscopic, calorimetric and diffraction methods. This is not only fundamentally important, but it also has far-reaching consequences for applications and materials synthesis. Another important reason that has recently contributed to bring chiral smectics into focus again is that there are some very important but still unanswered fundamental questions connected with the coupling between polarity, chirality and symmetry. The chirality in smectic C phases is usually induced by using ‘rod-shaped’ molecules bearing a chiral center as building blocks, but recently achiral ‘bow-shaped’ or ‘banana’ molecules which form chiral smectic phases have received much attention.

For the investigation of the behavior of chiral smectic liquid crystals many spectroscopic and diffractometric techniques are used. Among them, NMR has already played and will play in the near future a major role. The structure of the mesogenic molecules, the orientational order, the structure of the aggregates, their tilt angle and magnetic alignment, as well as the structural changes at the phase transitions, are typical subjects which can be tackled with NMR. Moreover, relaxation studies allow the overall dynamics of mesogenic molecules, as well as internal and collective motions, to be investigated.

In this context, ^{13}C and ^2H NMR spectroscopies have almost exclusively contributed to structural and ordering studies, while ^1H relaxation dispersion measurements, ^{13}C and ^2H linewidth and relaxation studies have been employed to characterize the dynamics. Moreover, it should be mentioned that a specific structural role (e.g., in determining biasing of internal motions) has been played by ^{14}N NQR techniques.¹

2 MOLECULAR ALIGNMENT

In the NMR of liquid crystals it is important to clarify the alignment behavior of the directors with respect to the external magnetic field. When S_C phases are obtained by lowering the temperature either from nematic or S_A phases, where the director was aligned along the external magnetic field, two types of behavior can be found: (i) the directors prefer to

Figure 1 Scheme of different chiral smectic phases: (a) ferroelectric S_C^* , (b) anti-ferroelectric S_{CA}^* , (c) $S_{C\alpha}^*$, (d) ferroelectric $S_{C\gamma}^*$. (Reproduced by permission of American Physical Society and Professor R. Blinc from M. Skarabot, M. Cepic, B. Zeks, R. Blinc, G. Heppke, A. V. Kityk and I. Musevic, *Phys. Rev. E*, 1998, **58**, 575)

remain aligned along the magnetic field and the smectic layers tilt with respect to the field; (ii) the layers remain perpendicular to the magnetic field and the directors progressively tilt as the temperature is lowered. In the case of S_C^* the alignment is commonly governed by the chirality: in the case of high optical purity the smectic layers keep normal to the magnetic field as in the S_A phase, and the directors tilt away from the field direction within each layer and give rise to a helical structure going through the layers. However, this is not a general rule: situations where the director keeps aligned to the field, causing unwinding of the helical structures (u- S_C^*) are present and, in particular cases, a ‘magnetic’ transition between u- S_C^* and S_C^* can be observed within the ferroelectric range. Helix unwinding has also been found in the case of chiral smectic phases induced by chiral host molecules. When the liquid crystal is formed by racemic mixtures, the directors usually behave as in achiral smectogens, remaining aligned to the field while the smectic layers tilt. On the other hand, in the case of S_{CA}^* the directors are not aligned to the field for both

optically pure samples and racemic mixtures. A particular case is that of fast spinning conditions (with a rate of the order of a kHz) about an axis not parallel to the magnetic field direction: the molecular director usually aligns along the spinning axis even for optically pure samples, but cases of partial retention of the helical structure have been observed.

3 STRUCTURE AND ORIENTATIONAL ORDERING: ^2H METHODS

Deuterium NMR in partially deuterated liquid crystals is an extremely powerful tool for the determination of orientational order at the molecular level, as well as for the study of the organization of liquid crystalline superstructures. In the case of FLC, AFLC and related phases, deuterium NMR has been used for the investigation of phase transitions, structural, geometrical, conformational and dynamic behavior of chiral mesogens, as well as of the helix structure and its distortion in the presence of external fields.

The deuterium nucleus has a spin $I = 1$, thus exhibiting a non-zero electric quadrupole moment (eQ). The quadrupolar Hamiltonian is the main perturbation to the Zeeman term: it does not contribute to ^2H spectra of isotropic phases, since it is traceless, but it dominates those of oriented phases. Here, large quadrupolar splittings $\Delta\nu_q$ can be observed depending on the local order parameters S_{ii} defined in the principal axis system (a, b, c) for the electric field gradient tensor:

$$\Delta\nu_q = \frac{3}{2}q_{aa} \left[S_{aa} + \frac{\eta}{3} (S_{bb} - S_{cc}) \right] \quad (1)$$

where the a axis is along the C–D bond, $q_{aa} = e^2qQ/h$ is the quadrupolar coupling constant and $\eta = (V_{bb} - V_{cc})/V_{aa}$ is the asymmetry parameter, which is usually small due to the almost axial symmetry of the local electric field gradient tensor V . Neglecting η , equation (1) reduces to the simplified form:

$$\Delta\nu_q = \frac{3}{2}q_{aa}S_{aa} \quad (2)$$

q_{aa} assumes typical values of about 200, 185 and 170 kHz for sp , sp^2 and sp^3 carbon hybridizations, respectively, and therefore local order parameters can be obtained in a straightforward way by simple quadrupolar splitting measurements.

Sometimes, dipolar splittings due to the coupling with adjacent protons or deuterons can also be directly measured or extracted from ^2H NMR spectra, and they can be related to local order on the basis of the following equation:

$$\Delta\nu_d = -2K \frac{S_{\alpha\alpha}}{r^3} \quad (3)$$

where $S_{\alpha\alpha}$ is the ordering matrix element in the direction of the internuclear vector, which can be expressed in terms of S_{aa} , S_{bb} and S_{cc} depending on the molecular geometry; K is a constant depending on the nucleus coupled to the deuteron considered and r is the corresponding internuclear distance.

The expression of the local order parameters in terms of molecular order parameters is quite complex in the general case because of the molecular flexibility. This problem has been tackled either by theories which take into account how the molecular order depends on molecular conformations or

Figure 2 Variable temperature ^2H spectra of (S)-10B1M7- d_2 experiencing S_A , S_C^* , S_C^* , S_CA^* and S_I^* phases. In this example, the spectra are taken on cooling every 5 degrees starting from 403 K (bottom)

by treating the spectral data in the framework of information theories (M.E. methods). In the oversimplified, but common, assumption of rigid molecular structure, local order parameters can be written in terms of the principal order parameter S_{zz} and molecular biaxiality ($S_{xx} - S_{yy}$) through a series of spherical harmonic projections which transform the local frame into the molecular one on the basis of the molecular geometry.

Therefore, the extraction of a set of quadrupolar and dipolar couplings from ^2H spectra, when suitably labelled samples are available, allows the evaluation of molecular geometry and orientational order of either molecular fragments or the whole mesogenic molecule in the whole liquid crystalline range (see Figure 2).

By means of these methods structural information, such as that the core of some ferroelectric mesogens has a bent structure,² or that the chiral chain in AFLCs is substantially bent (as much as 43°) with respect to the molecular long axis,³ have been found. In ferroelectric mesogens formed by two aromatic moieties joined by an ester bridge other subtle findings are that the two fragments show not only different principal local order parameters and biaxiality, but also different deuterium lineshapes within the same ^2H -NMR spectrum (Gaussian vs. Lorentzian). In principle, the tilt angle can be measured from the trend of the order parameter vs. temperature; however, since the measured order parameter in tilted phases is S_{zz} (the so-called ‘nematic order’) scaled by a factor $(3 \cos^2 \theta - 1)/2$, where θ is the tilt angle, this usually

requires an extrapolation of S_{zz} . In favorable cases, however, a precise evaluation of the tilt angle can be performed by making measurements at two different fields, giving rise to S_C^* (low field, helix wound and molecules tilted away from the field) and u-S_C^* (high field, helix unwound, molecules aligned to the field and measured order parameter coincident with S_{zz}).

The full power of deuterium NMR can be, however, exploited in angular dependent experiments, where spectra are recorded as a function of the angle ψ between the external magnetic field and the helicoidal axis, which is parallel to the smectic layer normals.⁴ In order to avoid the rearrangement of the molecules and the smectic planes with the field the sample is rotated at an angle ψ only during the short acquisition time and then quickly counterrotated to the initial position and again to $-\psi$ for the next acquisition. In this case the deuterium quadrupolar splitting is given by:

$$\Delta\nu_q = \frac{3}{4}q_{aa}S \left[3(\sin\psi \sin\theta \sin\phi + \cos\psi \cos\theta)^2 - 1 \right] \quad (4)$$

where S is the local order parameter relative to the director and ϕ is the director azimuth angle.

By means of this technique the soliton-like deformation of the helix and the critical magnetic field (i.e., the field causing helix unwinding) as a function of ψ can be studied. The soliton-like deformation has been found to have π and 2π symmetry for $\psi = 90^\circ$ and $\psi \neq 90^\circ$, respectively. The critical

magnetic field is anisotropic and it is minimum for ψ values ranging from 45 to 90°, as the tilt angle grows from 0 to 90°: reentrant $S_C^* \rightarrow S_C^* \rightarrow S_C^*$ behavior as a function of ψ has been experimentally observed.⁴

In the case of AFLC, the angular dependence of deuterium NMR spectra not only provides a microscopic verification of the alternating tilt model for S_{CA}^* phase, but it also highlights the presence of inter-layer molecular diffusion. In fact, from the point of view of angular dependent experiments, the antiferroelectric herringbone structure of the S_{CA}^* phase is similar to that of the non tilted S_A phase, as a result of the averaging of the electric field gradient tensor at the deuterium sites of two successive layers: this is produced by rapid molecular diffusion between adjacent layers followed by molecular reorientation corresponding to a 180° jump of the azimuth angle.

4 STRUCTURE AND ORIENTATIONAL ORDERING: ¹³C METHODS

¹³C techniques, and especially methods particular to solid state NMR, such as Magic Angle Spinning (MAS) and Cross-Polarization (CP), are useful to obtain insight into structural and orientational ordering information of chiral smectic liquid crystals. ¹³C experiments can be carried out in static conditions or by fast spinning the sample about an axis forming an angle φ with the external magnetic field. The latter are referred to as MAS (when $\varphi = 54.7^\circ$) or OFF-MAS experiments (when it deviates from that value). The molecular directors in tilted smectic phases can be aligned or unaligned to the magnetic field (static experiments), or to the spinning axis, depending on many factors, and a variety of behaviors have been observed, as previously discussed in Section 2.

¹³C static spectra can experience a remarkable increase in linewidths going from isotropic to smectic phases, with a consequent loss of resolution, since the restricted mobility in the latter phases causes the anisotropic interactions affecting the spectrum to be partially reduced, but not averaged out. This allows phase transitions to be clearly identified and, possibly, the changes in the dynamic processes associated with the transitions to be unraveled.

The chemical shift in the oriented phases is strongly affected by their orientational properties, and large shifts are observed going from the isotropic towards a smectic phase. In fact, the chemical shift σ in the liquid crystalline phase can be related to the isotropic chemical shift σ_i through the following equation:

$$\sigma = \sigma_i + \frac{2}{3} S_{zz} \left[\sigma_{zz} - \frac{1}{2} (\sigma_{xx} + \sigma_{yy}) \right] + \frac{1}{3} (\sigma_{xx} - \sigma_{yy}) (S_{xx} - S_{yy}) \quad (5)$$

where the σ_{ii} are components of the chemical shift tensor and the S_{ii} are the order parameters, i.e., the principal components of the ordering matrix in an assumed rigid molecule where the z axis coincides with the long molecular axis.

This equation reduces to the simplified form of equation 6 when the biaxiality $S_{xx} - S_{yy}$ is negligible with respect to S_{zz} ; $\Delta\sigma = \sigma_{zz} - 1/2 (\sigma_{xx} + \sigma_{yy})$ is the difference between the component of the chemical shift tensor along the direction

of the long molecular axis and the average component in the perpendicular plane.

$$\sigma \approx \sigma_i + \frac{2}{3} S_{zz} \Delta\sigma \quad (6)$$

Since $\Delta\sigma$ is positive for aromatic carbons and negative for aliphatic ones, a shift towards high and low frequencies is expected, respectively, in consequence of an increase of the order parameter S_{zz} , as, for instance, at the I- S_A and S_A - S_C transitions. However, when a chiral S_C phase is entered, the occurrence of the molecular tilting reduces the order parameter S_{zz} by the factor $(3 \cos^2 \theta - 1)/2$.

Therefore, in principle, the simple analysis of ¹³C spectra should allow order parameters to be calculated. To this aim, two main problems need to be overcome. First, static conditions can prevent obtaining high-resolution spectra in the smectic phases, thus requiring the use of fast spinning and high-power decoupling. Even in this case, however, the large changes in chemical shifts usually make the interpretation of the ¹³C spectrum difficult in the oriented phases on the basis of the sole spectrum of the isotropic phase, thus requiring chemical shift calculations, additional NMR experiments, such as cross-polarization, and, possibly, the preparation of suitably labeled samples. Second, in order to get S_{zz} from chemical shifts, the principal components of the chemical shift tensor have to be known (see equation 5). Since these quantities are not easily accessible, estimated values can be used, introducing, however, a large degree of uncertainty on the calculated order parameter values. Alternatively, the determination of the principal components of the chemical shift tensor can be performed for each carbon nucleus in the solid state by means of the 2D-TOSS-deTOSS experiment,⁵ which gives a spinning sideband pattern for each resolved resonance in the isotropic ¹³C spectrum.

A different approach is followed by Poon and Fung, who use the 2D-Separated Local Field (SLF) technique, which gives carbon-proton dipolar splittings ($\Delta\nu$) for each resolved resonance in the spectrum (see Figure 3).⁶ The following equation can be used to determine the dipolar coupling constants D :

$$\Delta\nu = f \left[(3 \cos^2 \theta - 1) D + J \right] \quad (7)$$

where f is a scaling factor characteristic of the dipolar decoupling sequence used and J is the C-H scalar coupling constant. The dipolar coupling constants so obtained can be exploited to determine the local order parameters through suitable relationships depending on the geometry and accessible conformations of the moiety which the C-H couple belongs to. This technique can also be used in combination with fast spinning at $\varphi \approx 45^\circ$ to obtain more resolved ¹³C spectra and remarkably reduce the proton-proton dipolar couplings. As a consequence, the experiments can be carried out with a lower decoupling power, thus reducing the temperature gradients in the sample and increasing the accuracy of the results.

The application of these techniques, also in combination with other ¹³C experiments, has allowed some important structural aspects of chiral smectic phases to be understood. In agreement with abovementioned ²H findings, in AFLCs the chiral chain is found to be bent with respect to the molecular long axis by an angle of as much as 43° not only in the

Figure 3 Application of the ^{13}C 2D-SLF technique to a ferroelectric liquid crystal. (Reproduced by permission of American Institute of Physics from C.-D. Poon and B. M. Fung, *J. Chem. Phys.*, 1989, **92**, 7392)

ferro- and anti-ferroelectric phases, but also in the less ordered ones, and even in the isotropic phase.⁷ Indeed, remarkable conformational changes are neither observed for optically pure mesogens throughout the liquid crystalline range, nor between optically pure mesogens and corresponding racemic mixture, thus supporting the conclusion that no new ‘chiral interactions’ should be invoked to explain the occurrence of chiral S_C phases, which should rather be governed by general excluded volume and/or electrostatic interactions.⁸

5 DYNAMICS: ^1H , ^{13}C AND ^2H METHODS

Dynamics in chiral smectogens by NMR is still a widely unexplored field due to the scarce experimental data so far reported in the literature and, to some extent, to the absence of theoretical models which might allow a more quantitative interpretation of these data. The papers published on this subject are mainly concerned with ^1H , ^{13}C or ^2H linewidths or spin-lattice relaxation time measurements. Each of these techniques highlights particular information, and therefore an overview on the dynamic behavior in chiral smectic phases can be obtained from their comparison.

5.1 ^1H

Proton spin-lattice relaxation measurements represent an important field in the investigation of the dynamics of chiral smectic phases. Some papers were published in the 80’s reporting measurements at different Larmor frequencies using conventional NMR spectrometers, but a great boost in this kind of measurements took place when fast field cycling spectrometers, able to extend the Larmor frequency range down to a few Hz, became available. ^1H T_1 measurements covering the range 100 Hz–300 MHz are performed using fast field cycling devices and conventional NMR pulsed spectrometers for the very low frequency range (between 100 Hz and 10 MHz) and above 10 MHz, respectively.⁹

The relaxation is essentially determined by the modulation of the dipolar couplings between neighboring protons in the more rigid parts of the molecules by motions having characteristic frequencies of the order of the Larmor frequency. In the frequency range usually investigated three main kinds of dynamic processes are involved: collective motions, molecular self-diffusion (SD) and local molecular rotations. Collective motions in chiral smectics include, in principle, order director fluctuations (ODF) and Goldstone and soft modes;¹ however, the Goldstone mode has a characteristic frequency too low to be detected by this kind of measurement, and the contribution of the soft mode cannot be clearly distinguished from that of ODF, so collective motions are usually treated in terms of ODF only. On this basis, the proton spin-lattice relaxation rate ($1/T_1$) can be expressed as a sum of terms, neglecting the contribution of possible cross terms between the different mechanisms, also considering that they usually show characteristic frequencies of different order of magnitudes:

$$\frac{1}{T_1} = \frac{1}{T_{1\text{ODF}}} + \frac{1}{T_{1\text{SD}}} + \frac{1}{T_{1\text{Rot}}} \quad (8)$$

As far as ODF are concerned, a frequency dependence of the type $T_1 \propto \omega$ is predicted for smectic phases by the model developed by Blinc et al.¹⁰ The contribution of molecular SD and rotations can be expressed on the basis of a number of theoretical models; an Arrhenius dependence is usually assumed for correlation times and diffusional coefficients.

Two ranges of frequency are generally identified: at frequencies lower than 100 kHz the predominant contribution to the relaxation is represented by collective motions, while above that limit molecular rotations and SD become by far the most important relaxation mechanisms. Recently, it has been observed that the proton relaxation behavior in both ferri and anti-ferroelectric smectic C^* phases differs remarkably from that in smectic A and ferroelectric smectic C^* phases. A further dynamic process, the anti-phase azimuthal angle fluctuations, corresponding to an additional term in equation 8, can be invoked to get a good reproduction of the experimental T_1 data (see Figure 4). This process mostly contributes to the relaxation below 20 kHz, along with director fluctuations.

The main limitation of ^1H techniques is their difficulty in achieving site-specific information and therefore in getting insight on the dynamics of molecular fragments. This limitation can be removed, in principle, by using ^{13}C and ^2H techniques.

5.2 ^{13}C

Some studies have been reported in which the dynamics of ferro- and/or anti-ferroelectric liquid crystals have been investigated through ^{13}C NMR solid state techniques. In fact, the high spectral resolution that can be achieved by

MAS and high-power decoupling usually allows distinct peaks corresponding to the different carbon nuclei to be singled out, thus obtaining detailed dynamic information. Linewidth and relaxation time measurements can be exploited to obtain information on motions with correlation times of the same order of magnitude to the inverse of the proton decoupling and the Larmor frequency, respectively. In some cases, linewidth studies as a function of temperature highlight the presence of line broadening in the chiral smectic C phases for aromatic ^{13}C only, the linewidth of aliphatic carbon nuclei remaining substantially unchanged over the whole mesophasic range, thus revealing remarkably different internal motions between the aromatic core and both the aliphatic chains. ^{13}C T_1 measurements do not reveal any appreciable change in the MHz dynamics at the $S_A - S_C^*$ transition (see Figure 5), the only exception being represented by a change in the slope of the $\ln(T_1)$ vs $1000/T$ trend in the S_{CA}^* phase for the sole chiral carbon nucleus.

5.3 ^2H

Studies of the dynamics of liquid crystals based on the analysis of ^2H Zeeman (T_{1Z}) and quadrupolar (T_{1Q}) spin-lattice relaxation times have been extensively reported in the literature.¹¹ In fact, deuterium relaxation times, for the measurement of which the use of high-resolution solid-state devices is not necessary, are mainly determined by the intramolecular quadrupolar interaction, and therefore their interpretation is not complicated by intermolecular interactions, as

Figure 5 ^{13}C T_1 temperature dependence of some carbon nuclei from aromatic core, chiral and achiral chains of an anti-ferroelectric liquid crystal. (Reproduced by permission of the Institute of Pure and Applied Physics from K. Tokumaru, B. Jin, S. Yoshida, Y. Takanishi, K. Ishikawa, H. Takezoe, A. Fukuda, T. Nakai and S. Miyajima, *Jpn. J. Appl. Phys.*, 1999, **38**, 147)

Figure 6 Logarithmic plots of ^2H spectral densities J_1 (full symbols) and J_2 (empty symbols) vs $1000/T$ in the different smectic phases of (a) MBHB and (b) 10B1M7 deuterated at two different aromatic core sites (triangles and circles indicate deuterons on the phenyl and biphenyl fragments, respectively). (Reproduced by permission of the American Chemical Society from D. Catalano, M. Cifelli, M. Geppi and C. A. Veracini, *J. Phys. Chem. A*, 2001, **105**, 34)

for proton relaxation. Moreover, their site-specificity allows clearly distinguished information arising from different molecular moieties to be obtained when suitably labeled samples are available. T_{1Z} and T_{1Q} are simply related to the spectral densities $J_1(\omega_0)$ and $J_2(2\omega_0)$ by means of the following equations:

$$\frac{1}{T_{1Z}} = J_1(\omega_0) + 4J_2(2\omega_0) \quad (9)$$

$$\frac{1}{T_{1Q}} = 3J_1(\omega_0) \quad (10)$$

Several models can be applied which allow these spectral densities to be expressed in terms of quantitative parameters (e.g., diffusional coefficients and activation energies) describing specific internal, overall molecular and collective motions. Unfortunately, the models available for molecular motions are based on molecular and phase symmetry assumptions which do not properly apply to chiral smectic C phases. However, even though in these phases the interpretation of ^2H spin-lattice relaxation times cannot be as detailed and quantitative as in nematic and smectic A phases, these measurements can contribute to unraveling the MHz dynamic behavior of FLC and AFLC. No particular changes in T_{1Z} and T_{1Q} are observed at the $S_A-S_C^*$ transition for deuterium nuclei belonging to the aromatic core, even though a change in the slope of the $\ln(J)$ trend vs $1000/T$ can be revealed within the anti-ferroelectric range (see Figure 6).¹² These results correspond with the ^{13}C T_1 findings previously discussed. Deuterium relaxation studies of both the chiral and achiral chains should help to clarify the extent to which internal and/or molecular motions are biased when ferroelectric and anti-ferroelectric phases are entered.

Occasionally, dynamic information can also be extracted from the analysis of variable-temperature ^2H spectra. For instance, a different dynamic behavior between the two aliphatic chains was observed from the occurrence of multiplets in the spectrum, ascribable to an asymmetric hindering of rotations about C–C bonds in the chiral chain. Moreover, the presence of a maximum line broadening for aromatic deuteriums in the middle of the chiral smectic C range (see Figure 2), probably highlights the same dynamic behavior revealed by the previously mentioned ^{13}C line broadening.

Summarizing, ^1H , ^{13}C and ^2H results strongly support the conclusion that no abrupt change in the fast overall dynamics in the MHz regime occurs as the smectic C^* phase is entered, these motions slowing down continuously by decreasing the temperature and being more hindered within the anti-ferroelectric phase. On the other hand, particular dynamic behavior has been observed in a slower regime for both the chiral chain and the aromatic core in the chiral smectic C phases. These findings could contribute to explaining the occurrence of these phases as well as their peculiar characteristics.

1 INTRODUCTION

Rowell and co-workers^{1,2} were first to demonstrate that deuterium is an excellent spin probe for studying liquid crystalline samples. They also used selectively deuterated compounds to simplify the proton NMR spectra. Early work in this field was devoted to measuring and interpreting spin-lattice relaxation rates³ of protons, and to revealing orientational ordering in various mesophases⁴ by means of deuterium splittings and spectral patterns. While proton NMR of liquid crystals shows broad partially resolved spectra, the deuterium NMR spectra are often characterized by well resolved quadrupolar doublets^{5,6} that may contain some dipolar fine structures [Figure 1(a)]. The deuteron ($I = 1$) Zeeman levels [Figure 1(b)] are perturbed by interaction of its nuclear quadrupolar moment Q with the asymmetric EFG at the deuteron site. The static Hamiltonian $\hat{\mathcal{H}}_0$ of the system is defined by

$$\hat{\mathcal{H}}_0 = \hat{\mathcal{H}}_Z + \langle \hat{\mathcal{H}}_Q(t) \rangle \quad (1)$$

where $\hat{\mathcal{H}}_Z$ is the Zeeman Hamiltonian and $\hat{\mathcal{H}}_Q$, the quadrupolar Hamiltonian, is time dependent due to thermally driven, randomly fluctuating molecular processes. Due to a nonzero $\langle \hat{\mathcal{H}}_Q(t) \rangle$ in a partially ordered system, the two nuclear transitions are displaced at equal distances from the Larmor frequency ($\omega_0/2\pi$) as shown in Figure 1. The EFG tensor for most C–D bonds is axially symmetric, with the unique principal axis along the C–D bond direction. The quadrupolar splitting for a static C–D bond can take a maximum value of $\frac{3}{2}\chi$ or about 260 kHz, which is much less than its Larmor frequency of 46 MHz in a magnetic field of 7.1 T. For comparison, dipolar splitting between two deuterons in a methylene group is at most a few kilohertz, D–H dipolar splitting for a similar geometry is about 10 kHz, and the chemical shift is of the order of 1 kHz. It is therefore possible to neglect the chemical shift dispersion and the dipolar interaction with other nuclei and to treat the deuteron as an isolated spin-1 nucleus. The theoretical analysis of such a system is relatively simple. The quadrupolar splitting $\Delta\nu_i$ of the i th C–D bond may be approximated by^{7,8}

$$\Delta\nu_i = \frac{3}{2}\chi S_{zz}(3\cos^2\theta_i - 1)/2 \quad (2)$$

Figure 1 (a) The structure of MBBA and a typical deuterium NMR spectrum of MBBA- d_{13} in its nematic phase. (b) Energy level diagram of a deuteron spin ($\eta = 0$) in a large magnetic field. $\omega_0/2\pi$ is the Larmor frequency

where the contribution from the $S_{xx} - S_{yy}$ term is neglected, S_{zz} is the orientational order parameter of the long molecular axis with respect to the nematic director (see below), and θ_i represents the angle between the C_i –D bond and the molecular z axis. The angular brackets denote a statistical average over all allowed conformations in a flexible mesogen.

Spin relaxation has long been recognized as a useful technique for studying dynamic processes in liquid crystals.^{7,8} A partial list of such processes⁸ includes the order director fluctuations (ODFs), translational diffusion, order parameter fluctuations near phase transitions, molecular reorientation, and internal rotations of alkyl end chains. Deuteron is particularly suitable for getting detailed information about molecular motion in liquid crystals, since its relaxation is governed by intramolecular mechanisms, and multipulse techniques⁷ may be used to determine individual spectral densities of motion from partially relaxed deuteron NMR spectra for all the resolved doublets. The quadrupolar relaxation Hamiltonian for a spin-1 system is defined by the time dependent part of $\hat{\mathcal{H}}_G(t)$ with respect to its average value $\langle \hat{\mathcal{H}}_Q(t) \rangle$:

$$\hat{\mathcal{H}}'_Q(t) = \hat{\mathcal{H}}_Q(t) - \langle \hat{\mathcal{H}}_Q(t) \rangle \quad (3)$$

The deuteron spin-lattice relaxation rates are given by^{9,12}

$$\frac{1}{T_{1Z}} = J_1(\omega_0) + 4J_2(2\omega_0) \quad (4)$$

$$\frac{1}{T_{1Q}} = 3J_1(\omega_0)$$

where an axially symmetric quadrupolar interaction ($\eta = 0$) is assumed. The spectral densities of motion J_{mL} ($m_L \omega_0$) are Fourier transforms of the autocorrelation functions $G_{mL}(t)$ which involve second-rank tensor components $D_{mL0}^2(\Omega(t))$ in the relaxation Hamiltonian. The part of $\hat{\mathcal{H}}'_Q(t)$ that connects spin states with $\Delta m_I = 1$ has a fluctuation spectrum described by $J_1(\omega_0)$, while the part that connects states with $\Delta m_I = 2$ is described by $J_2(2\omega_0)$. These spectral parameters and $J_0(0)$ at zero frequency (obtained in principle from one quantum spin echo or quadrupolar echo experiments) are determined without a particular choice of motional model. They must be accurately measured as a function of temperature at different Larmor frequencies, and may be used to provide critical tests of any proposed model of molecular motion. For systems with coupled deuterons, there are additional terms^{13,14} in the relaxation expressions that arise from cross-correlation functions describing pairwise correlation in the motion of EFG tensor components at each deuteron. This additional information may serve as a further check of the proposed motional model.

2 ORIENTATIONAL ORDERING

One of the common features in liquid crystals is the existence of a preferred orientation of molecules along a spatial direction specified by a unit vector known as the director $\mathbf{n}$. Deuteron NMR spectroscopy has played a major role in establishing molecular field theories^{8,15,16} for liquid crystals. These mean field theories can predict the temperature dependences of order parameters of rigid solutes and solvent molecules. The ordering of molecules in mesophases may in general be described by an orientational distribution function $f(\Omega)$ which depends on Eulerian angles $\Omega(\equiv \phi, \theta, \psi)$. The $f(\Omega)$ can be expanded in terms of Wigner rotation matrices of rank L

$$f(\Omega) = \sum_{L=0}^{\infty} \sum_{m,m'=-L}^L \frac{2L+1}{8\pi^2} a_{Lm'm} D_{m'm}^L(\Omega) \quad (5)$$

where the expansion coefficients $a_{Lm'm} = \langle D_{m'm}^{L*}(\Omega) \rangle$ are the microscopic order parameters of rank L . The order parameters of rank two and four can in principle be measured, but higher rank order parameters are not as easily accessible by experiments. The potential of mean torque $V(\Omega)$ can be defined by writing $f(\Omega)$ as

$$f(\Omega) = \exp[-\beta V(\Omega)] / \int d\Omega \exp[-\beta V(\Omega)] \quad (6)$$

where $\beta = 1/k_B T$. $V(\Omega)$ represents the orientational potential of a single molecule. In the Maier-Saupe theory^{17,18} of nematics, $V(\Omega)$ takes on a simple form:

$$V(\cos \theta) = -\epsilon \langle P_2(\cos \theta) \rangle P_2(\cos \theta) \quad (7)$$

where the parameter ϵ scales the strength of intermolecular interaction. The theory used a mean field approach and assumed that attractive dispersion forces among molecules are responsible for the nematic order. It was successful in

predicting a first-order phase transition between a nematic and an isotropic phase, as well as the temperature dependence of the nematic order parameter $\langle P_2 \rangle (\equiv S_{zz})$. Using equation (2) as a first approximation, $\langle P_2 \rangle$ can be calculated^{1,2} from the observed quadrupolar splittings in liquid crystals. A general set of 25 rank-two order parameters⁸ was defined by Saupe:

$$S_{ij}^{\alpha\beta} = \frac{1}{2} \langle 3i_{\alpha} j_{\beta} - \delta_{\alpha\beta} \delta_{ij} \rangle \quad (8)$$

where (α, β) refer to a space-fixed axis system (X, Y, Z) , (i, j) refer to a molecule-fixed axis system (x, y, z) , i_{α} denotes the projection of a unit vector $\mathbf{i}$ along the α axis, and the angular brackets represent an ensemble average. For uniaxial phases where $\mathbf{n} \parallel Z$ axis, equation (8) gives the simple Saupe order matrix $S_{ij} (= \frac{1}{2} \langle 3i_z j_z - \delta_{ij} \rangle)$.

2.1 Rigid Molecules in Uniaxial Phases

For a rigid molecule (or a rigid fragment of a molecule) ordered in a uniaxial liquid crystalline phase, the partially averaged component $\langle A_{\parallel} \rangle$ parallel to the director of any second rank tensor $\mathbf{A}$ is given by

$$\langle A_{\parallel} \rangle = A_0 + \frac{2}{3} \sum_{ij} A_{ij} S_{ij} \quad (9)$$

where A_0 is the isotropic average of $\mathbf{A}$. For the EFG tensor $\mathbf{q}$, A_0 is zero and the splitting $\Delta\nu = \frac{3}{2} e^2 Q / h \langle q_{\parallel} \rangle$ can be calculated using equation (9). The unknown S_{ij} elements can be determined from measuring enough independent values of $\langle q_{\parallel}^i \rangle$ where the superscript refers to sites in a molecule. This is usually possible for a rigid solute dissolved in a liquid crystal, where the principal axes of symmetry of the solute may be located with certainty based on its molecular symmetry. Hence deuterium NMR can provide precise measurements of S_{zz} and $S_{xx} - S_{yy}$ for a rigid molecule. Figure 2 illustrates the determination of $S_{xx} - S_{yy}$ and S_{zz} for anthracene- d_{10} in several nematogens. The solid curves are predictions based on the mean field theory of biaxial solutes where the λ parameter is a measure of the deviation in molecular symmetry of the solute from cylindrical symmetry. That the solute ordering depends on the solvent is an indication that the solute-solvent interactions cannot be dominated only by dispersion forces. For flexible mesogens, it may be possible to determine a local order matrix for a rigid fragment of the molecule provided the principal axes can be located on the fragment based on its symmetry. This is often difficult due to a lack of measurable nuclear couplings. A clear exception to this is the study of a perdeuterated fluorene group in the mesogen 2-fluorenyl-4'-tetradecyloxy benzoate- d_9 (FLOG₄).²⁰ Because of the large number (eight) of distinct deuteron sites, the location of the long molecular axis could be adjusted for the average conformer in a frame fixed to the fluorene group, and the local order parameters were unambiguously determined.

2.2 Flexible Molecules in Uniaxial Phases

Mesogenic molecules are usually composed of an aromatic core and one or more flexible alkyl chains. Due to internal

Figure 2 (a) Molecular structure of anthracene- d_{10} and the deuterium spectrum at 30.7 MHz from deuterons 1, 4, 5, 8, 9, and 10 in anthracene- d_{10} dissolved in Phase V. (b) Variation of S_{zz} with $S_{xx} - S_{yy}$ for anthracene- d_{10} dissolved in ZLI 1167 ($\square$), E9 ($\circ$) and Phase V ($\diamond$).¹⁹

rotations, the chain does not always exist in an all-*trans* conformation. It is generally accepted that a single order tensor may not be enough to describe orientational ordering of different configurations. In equation (9), the average of $A_{\parallel}$ must also be carried out over an ensemble of molecules having all allowed configurations. The rotational isomeric state (RIS) model of Flory²¹ is used to generate all chain configurations. Since a single $A_{\parallel}$ value would not provide quantitative information on the orientational order of the molecules, a molecular model is therefore required. Such a model using the additive potential method^{15–19} was pioneered by Marcelja and later improved by Emsley and Luckhurst. The potential of mean torque which is responsible for the alignment of a conformer has its origin from the molecular field of its neighbors. It is constructed by adding up local interaction tensors of the carbon-carbon segments and the rigid aromatic core segment, which are specified by model parameters X_c and X_a , respectively. Each rigid (n th) conformer has its own order matrix S^n and its equilibrium probability of occurrence $P_{eq}(n)$. Equilibrium statistical mechanics is used to do the ensemble average in calculating the quadrupolar splittings $\Delta\nu_i$. The parameters X_c , X_a and E_{tg} (the energy difference between a *gauche* and a *trans* state) are varied to optimize the fits to the

Figure 3 Plot of $\langle P_2 \rangle$ versus $\langle S_{xx} \rangle - \langle S_{yy} \rangle$ for the averaged MBBA molecule.²²

experimental splittings.⁸ For example, such analysis²² has been carried out for the splittings of MBBA (Figure 1). Knowing $S_{\alpha\beta}^n$ and $P_{eq}(n)$, it is possible to find a conformationally average order matrix $\langle S \rangle$ by doing the statistical average in a common molecular frame. The principal components $\langle P_2 \rangle$ and $\langle S_{xx} \rangle - \langle S_{yy} \rangle$ of the ‘average’ molecule can be obtained by diagonalizing the $\langle S \rangle$ matrix. Figure 3 shows the plot of $\langle S_{xx} \rangle - \langle S_{yy} \rangle$ versus $\langle P_2 \rangle$ of MBBA. It is interesting to note that the molecular biaxial order parameter, $\langle S_{xx} \rangle - \langle S_{yy} \rangle$, of the ‘average’ molecule is quite small for this flexible mesogen.

2.3 NMR in Biaxial Phases

Biaxial nematics, some smectic phases, such as S_G , and certain discotic phases⁸ show phase biaxiality. Deuterium NMR may be used to detect phase biaxiality through the measurement of a nonzero motionally induced asymmetry parameter η^{LC} in the nuclear quadrupolar interaction whose EFG may have $\eta = 0$ in the solid state. Suppose that the molecule is rigid and the principal axes (X, Y, Z) of the liquid crystalline phase are chosen to coincide with the principal axes of the average EFG tensor. Letting the polar angles of the magnetic field in the (X, Y, Z) system be (θ_0, ϕ_0) , the splitting is given by⁸

$$\delta\nu(\theta_0, \phi_0) = \frac{3}{4}\chi^{LC}\{(3\cos^2\theta_0 - 1) + \eta^{LC}\sin^2\theta_0\cos 2\phi_0\} \quad (10)$$

where χ^{LC} , a motionally averaged quadrupole coupling constant, and η^{LC} are defined by

$$\chi^{LC} = \chi \sum_m \overline{D_{0,m}^2(\theta, \psi) D_{m,0}^2(\beta, \alpha)} \quad (11)$$

$$\eta^{LC} = \sqrt{\frac{3}{2}} \frac{\chi}{\chi^{LC}} \sum_m [\overline{D_{2,m}^2(\phi, \theta, \psi)} + \overline{D_{-2,m}^2(\phi, \theta, \psi)}] D_{m,0}^2(\beta, \alpha)$$

where (ϕ, θ, ψ) are Euler angles that transform between a molecular frame (x, y, z) and the liquid crystalline (X, Y, Z)

Figure 4 Experimental angular dependence of the deuterium NMR spectrum in the S_G phase of 5O.7- d_4 (aniline ring deuterated) at 31 °C.²⁴

frame, and (β, α) are the polar angles of the C–D bond in the molecular frame. Phase biaxiality is reflected by $D_{\pm 2, m}^2$ in η^{LC} , and the effect of η^{LC} on $\Delta\nu$ is maximum when the director is oriented normal to the magnetic field (i.e. $\theta_0 = 90^\circ$). It is noted that symmetry considerations involving both the nature of the molecules and of the liquid crystalline phases can considerably simplify the evaluation of the order parameters $D_{m', m}^2(\phi, \theta, \psi)$. η^{LC} takes on a simple form if the (x, y, z) frame is chosen to be the principal frame of the order matrix. Further simplification can be made if the molecule is a cylindrical rod [$m = 0$ in equation (11)]. Then

$$\chi^{LC} = \chi S_{zz}^{ZZ} (3 \cos^2 \beta - 1)/2$$

$$\eta^{LC} = \sqrt{\frac{3}{2} [D_{2,0}^2 + D_{-2,0}^2]} / S_{zz}^{ZZ} = (S_{zz}^{XX} - S_{zz}^{YY}) / S_{zz}^{ZZ} \quad (12)$$

The $S_{zz}^{XX} - S_{zz}^{YY}$ term represents anisotropic fluctuations of the molecular z axis relative to the principal axes (X, Y, Z) of the average EFG tensor. Edge singularities (Figure 4) are predicted for the spectral pattern when $\theta_0 \neq 0$. The separation between edge singularities at $\theta_0 = 90^\circ$ is a direct measure of η^{LC} . Such a spectral pattern was first observed in an S_G phase²³ with a deuterated solute in the mesogen 6O.6. A η^{LC} value of 0.2 was obtained²⁴ in the S_G phase of 5O.7- d_4 (Figure 4). Phase biaxiality had been investigated in other smectic phases by Doane²⁵ and in discotics by Luz.²⁶

3 SPIN RELAXATION AND MOLECULAR MOTION

Both nuclear spin–lattice and spin–spin relaxation rates are governed by random motion of spin-bearing molecules. Typically, a molecule remains in one state of motion for a short time (10^{-10} – 10^{-12} s). After this time, it suffers a collision with one of its neighbors, which changes its state of motion. When the molecule persists in some state of motion for a time of 10^{-10} s, its motional frequency spectrum is expected to contain components ranging from zero to 10^{10} Hz, which are covered by typical NMR experiments. Several dynamic processes are known to cause deuteron spin relaxation in liquid crystals. The process known as director fluctuations is unique to liquid crystals and was first used to explain light scattering from liquid crystals. Other processes include order parameter fluctuations, molecular reorientation, and internal rotations. The latter two motions involve individual molecules as in normal liquids, while director fluctuations involve collective motions of a large number of molecules. These collective motions are influenced by macroscopic properties like elastic

constants and anisotropic viscosities of the liquid crystalline medium. At best, director fluctuations can provide indirect information on the anisotropic interactions among molecules. On the contrary, molecular motion must reflect the shape of the instantaneous potential of mean torque on each molecule. Thus, it is sensitive to the nature of anisotropic interactions. Here, spin relaxation due to small cross terms between different processes will be ignored⁸ for simplicity.

3.1 Solute Dynamics

To avoid dealing with internal rotations, deuterated rigid solutes dissolved in thermotropic liquid crystals were studied^{7, 27} by spectral density measurements. Solute reorientation and director fluctuations were used to account for the observed frequency and temperature dependences of $J_1(\omega)$ and $J_2(2\omega)$. It is now well known that director fluctuations under the small-angle approximation produce a characteristic $\omega^{-1/2}$ dependence in $J_1(\omega)$ only. Reorientation motion is often described in terms of a symmetric top reorienting in an anisotropic potential of Maier–Saupe type using a small-step rotational diffusion model.⁸ This model uses a rotational diffusion tensor for the molecule which is diagonalized in a molecule-fixed frame. For weakly ordered solutes, their reorientation in a nematic solvent is often rapid to give frequency-independent spectral densities. For example, deuteron spin relaxation of *p*-diethynylbenzene (DEB- d_2 , deuterated in the two alkyne sites) in the nematic phase of Phase V⁷ clearly showed that $J_1(\omega)$ has a pronounced frequency dependence, while $J_2(2\omega)$ is essentially independent of frequency. This observation provides compelling evidence of director fluctuations in relaxing the deuterons in DEB- d_2 . Smectic phases can be used to provide higher ordering of solute molecules. Similar frequency behaviors for J_1 and J_2 were obtained for DEB- d_2 in the four mesophases of 4O.8. However, J_2 showed more frequency dependence when DEB- d_2 was dissolved in 8CB.⁸ A definitive explanation of the differences in these J_2 values has not yet been found. In general, analyses of experimental spectral density data would lead to rotational diffusion constants (or rotational correlation times $\tau_{\parallel}$, $\tau_{\perp}$) and a material factor A_{DF} that characterizes the strength of director fluctuations. For example, the ratio $\tau_{\perp}/\tau_{\parallel}$ is about 10 for DEB- d_2 in the nematic phase of Phase V.

3.2 Solvent Dynamics

The detection of director fluctuations in liquid crystals by means of deuteron spin relaxation in mesogens at conventional frequencies (10–50 MHz) has not met with success. This can be attributed to two factors: (1) the numerical value A_{DF} is small because most C–D bonds are oriented at an unfavorable angle to the long molecular axis; this is true for aromatic deuterons in mesogens such as 4-pentyl-4'-cyanobiphenyl (5CB), MBBA, etc., and (2) the contribution from director fluctuations to deuteron relaxation is masked by a much larger contribution due to relatively slow motions of large, sluggish molecules and fast internal motions within these molecules. To alleviate the difficulty associated with a small contribution from director fluctuations in the megahertz region, deuteron field cycling techniques have been applied²⁸

to several nematogens. The techniques involve fast switching of the Zeeman field between high- and low-field levels so that detection of the NMR signal is done at a high magnetic field while the spin system is allowed to relax in a low field (in the kilohertz region). These data seem to support the findings based on the proton field cycling studies of liquid crystals that director fluctuations are slow motional processes and are effective for spin relaxation only in the kilohertz region.

To treat deuteron spin relaxation of solvent molecules in the megahertz region it is often possible to ignore the small contribution from director fluctuations. This assumption is probably necessary in modeling spectral densities of motion for various deuterated sites in flexible mesogens. In particular, correlated internal rotations in flexible chains of liquid crystals are complex to treat theoretically. Furthermore, different motional models⁸ for reorientation of solvent molecules are possible. Besides the commonly used small-step rotational diffusion model, the anisotropic viscosity model of Freed and co-workers⁸ is a distinct alternative. Freed used a rotational diffusion tensor that is diagonalized in the director frame to reflect the anisotropic viscosity of the liquid crystalline medium. Another motional model known as the ‘third-rate’ model is a simple extension of the Freed model. It has a fast rotation around the long molecular axis in addition to its motions around and toward the director. Numerous deuteron relaxation studies have been carried out in recent years to investigate molecular motion in liquid crystals. Table 1 briefly summarizes thermotropic liquid crystals in which spectral density measurements were reported.

As an example, the spectral density data of MBBA at 15.3 and 46 MHz are reproduced in Figure 5. The data are typical for thermotropic liquid crystals studied thus far. Both $J_1(\omega)$ and $J_2(2\omega)$ decrease with increasing temperature and are frequency dependent with a weaker dependence in $J_2(2\omega)$. To account for the observed site dependences of $J_1(\omega)$ and $J_2(2\omega)$, a model is required to treat internal motions in the butyl chain. A superimposed rotations model³³ was used to describe fluctuations in the orientations of the C–D bonds due to overall and internal modes of motion in the chain-deuterated nematogen 5CB. Here the internal dynamics of the pentyl chain was treated by assuming that rotations about each C–C bond are independent of each other and could be superimposed onto the rotational diffusion of the whole molecule. This motional model is, however, unrealistic and inconsistent with how quadrupolar splittings were modeled using the RIS model of Flory. The RIS model has been extended^{42–44} to the time domain for liquid crystalline samples. A master

equation may be used to describe transitions among all allowed configurations in the alkyl chain. The model of Nordio and co-workers⁴⁴ is inherently complex because their master equation includes configuration dependent frictional effects. The solution of the rotational diffusion problem requires a matrix representation in the full space of angular and site functions. Because of the large dimensionality of their matrix representation, the computational effort was extremely demanding. The decoupled model⁴² of Dong uses three phenomenological rate constants to describe elementary jump modes: one-bond (k_1), two-bond (k_2), and three-bond (k_3) motions. The dimension of the rate matrix which is constructed in terms of these jump rate constants has the advantage of being much smaller. Both approaches,^{34,42–44} however, give similar theoretical predictions for 5CB regarding site and frequency dependences of $J_1(\omega)$ and $J_2(\omega)$ as well as the observed discontinuity³³ in the spin–lattice relaxation rates at the nematic–isotropic phase transition.

The decoupled model has been successfully applied²² to interpret the spectral densities of methylene deuterons (Figure 5) in MBBA, which are given by

$$J_{m_L}^{(i)}(m_L\omega) = \frac{3\pi^2}{2} \chi_i^2 \sum_{m_M} \sum_{n=1}^{27} c_{m_L m_M} \left| \sum_{l=1}^{27} d_{m_M 0}^2 (\beta_{M,Q}^{(i)l}) \exp[-im_M \alpha_{M,Q}^{(i)l}] x_l^{(1)} x_l^{(n)} \right|^2 \sum_j a_{m_L m_M}^{(j)} [(\tau_{m_L m_M}^{(j)})^{-1} + |\lambda_n|] / \{(m_L\omega)^2 + [(\tau_{m_L m_M}^{(j)})^{-1} + |\lambda_n|]^2\} \quad (13)$$

where $\beta_{M,Q}^{(i)l}$ and $\alpha_{M,Q}^{(i)l}$ are the polar angles of the C–i–D bond of the conformer l (there are 3^3 conformers in the butyl chain when the first dihedral angle at the junction of the aniline ring is allowed to sample three RISs) in a molecule-fixed frame whose z_M axis is along the ring *para* axis, λ_n and $\mathbf{x}^{(n)}$ are the eigenvalues and eigenvectors from diagonalizing a symmetrized rate matrix, $c_{m_L m_M}$ are the mean square of the Wigner rotation matrices, and the a , b and c coefficients are tabulated as functions of $\langle P_2 \rangle$ for a Maier–Saupe potential.⁴⁵ The correlation times $\tau_{m_L m_M}^{(j)}$ take on slightly different forms; the small-step rotational diffusion model uses

$$(\tau_{m_L m_M}^{(j)})^{-1} = [6D_{\perp}/b_{m_L m_M}^{(j)} + m_M^2(D_{\parallel} - D_{\perp})] \quad (14)$$

and the third-rate model uses

$$(\tau_{m_L m_M}^{(j)})^{-1} = h_{m_M} + [6D_{\beta}/b_{m_L m_M}^{(j)} + m_L^2(D_{\alpha} - D_{\beta})] \quad (15)$$

Solid curves denote theoretical predictions based on the third-rate model and three jump rates for internal rotation.²²

where $h_0 = 0$, $h_1 = D_\gamma$, and $h_2 = (3p + 1)D_\gamma$, with $p = 0$ corresponding to strong collision and $p = 1$ to small-step rotational diffusion for the γ motion. The D s are rotational diffusion constants that are principal components of the rotational diffusion tensor of an ‘average’ molecule. The methine (C-0) deuteron has no internal motion, and the C-0–D bond reflects the motion of the aromatic core, giving

$$J_{m_L}^{(0)}(m_L\omega) = \frac{3\pi^2}{2} \chi_0^2 \sum_{m_M} c_{m_L m_M} [d_{m_M 0}^2 (\beta_{M,Q})]^2 \times \sum_j a_{m_L m_M}^{(j)} [\tau_{m_L m_M}^{(j)}]^{-1} / [(m_L\omega)^2 + (\tau_{m_L m_M}^{(j)})^{-2}] \quad (16)$$

where $\beta_{M,Q}$ is the angle between the C–D bond and the z_M axis. Using equations (13) and (16), the fits between the calculated and experimental spectral densities are optimized by varying the rotational diffusion constants and the jump rate constants at each temperature.

Both the small-step rotational diffusion and third-rate models were examined. Both models were found to describe molecular reorientation of MBBA. The solid curves in Figure 5 are theoretical spectral densities based on equations (13) and (16) using $\tau_{m_L m_M}^{(j)}$ given by the third-rate model [equation (15)], X_a , X_c , and $\langle P_2 \rangle$ given by modeling the quadrupolar splittings ($E_{lg} = 2550 \text{ J mol}^{-1}$, $E_{g\pm g\pm} = 6000 \text{ J}$

mol^{-1}). D_α and D_β are roughly the same ($\approx 5 \times 10^7 \text{ s}^{-1}$ in the middle of the nematic phase), while D_γ is two orders of magnitude larger. D_α refers to the motion of the long molecular axis around the director, while D_β refers to its motion toward the director. These rotational diffusion constants decrease with decreasing temperature as expected for a thermally activated rotational process. The Nordio model has been used to derive motional parameters at different temperatures in 5CB³⁴ and 4-*n*-hexyloxy-4'-cyanobiphenyl (6OCB).³⁵ In studying the reorientation process in the smectogen 5O.7, the spectral densities of the methine and ring deuterons were measured as a function of temperature at two different Larmor frequencies in the megahertz region.³¹ It was found that the large frequency dependence in $J_1(\omega)$ can only be rationalized by including director fluctuations. The third-rate model seems to produce physical rotational diffusion constants in the nematic, smectic A, and smectic C phases of 5O.7.

4 NOVEL NMR EXPERIMENTS

Some applications of newer NMR techniques to the study of liquid crystalline samples are now outlined. The proton NMR spectra of solute molecules dissolved in liquid crystals are usually complex, and iterative fitting of the NMR spectra must be used to extract dipolar couplings. Spectral simplification is possible by using partially deuterated solutes instead. When this is not practical, multiple quantum NMR spectroscopy⁴⁶ can greatly simplify spectra of complex spin systems. Multiple quantum NMR is concerned with the observation of forbidden nuclear transitions, i.e. $\Delta m_I \neq 1$. Multiple quantum coherences can only be detected indirectly. To detect all orders of multiple quantum transitions, special forms of two-dimensional NMR (2D NMR) spectroscopy are required. The high-order multiple quantum spectrum is simple due to the decrease in number of nuclear transitions with increasing order. Multiple quantum transitions of deuterons are now described.

In oriented systems, the quadrupole Hamiltonian leads to a splitting of the single quantum transitions [see Figure 1(b)]. Double quantum spectra of a deuteron ($\Delta m_I = 2$) have the advantage of eliminating quadrupolar effects. This is obvious from the deuterium energy diagram for a spin-1 system, since the quadrupolar shifts on $m_I = 1$ and $m_I = -1$ energy levels are equal. Any coherence established between these two levels will evolve at twice the Larmor frequency (as modified by chemical shift). Single- and double-quantum spectra were used⁶ to study chain conformation in four members of the *n*O.7 series. It was noted that the distribution in the quadrupolar splitting is the dominant contribution to the deuteron linewidth of the single quantum spectrum. The distribution is due to a spread in the orientation of the long molecular axes in the liquid crystalline sample. Because a double quantum spectrum is not affected by quadrupolar effects, it has better spectral resolution and therefore may yield long-range dipole–dipole couplings among deuterons. Figure 6 shows a comparison of single- and double-quantum spectra of the α signal of 5O.7- αd_2 [Figure 6(a)] and the γ signal of 5O.7- $\alpha d_2 \gamma d_1$ [Figure 6(b) and (c)]. The improved resolution of the γ signal in the double quantum spectra is remarkable, and allows measurements of long-range deuterium dipolar couplings. For a two-coupled deuteron system, multiple quantum transitions can

Figure 6 Single quantum (left) and double quantum (right) spectra for (a) the α signal of 50.7- αd_2 at 57°C, and the γ signal in 50.7- $\alpha d_2 \gamma d_1$ at (b) 57°C and (c) 41°C, respectively. The stick diagrams give the corresponding theoretical spectra⁶

reveal the correlation of relaxation mechanisms acting on two deuterium nuclei. Besides the three autocorrelation terms $J_0^A(0)$, $J_1^A(\omega)$, and $J_2^A(2\omega)$, which describe the motion of the EFG tensor of either deuteron, the three cross-correlation terms $J_0^C(0)$, $J_1^C(\omega)$, and $J_2^C(2\omega)$ describe correlation between the motion of the two EFG tensors. There are many relaxation studies of deuterated solutes in thermotropic liquid crystals.^{13,14,27} For example, zero-, two-, and four-quantum linewidths may be used to determine the three cross-correlation terms^{13,14} in acetonitrile- d_3 .

2D NMR spectroscopy is now common in the study of liquid crystals. Using ^{13}C nuclei, the carbon–proton dipolar couplings can be obtained by means of the near magic angle spinning and the separated local field spectroscopy. Rapid sample spinning near the magic angle (54.7°) was incorporated to improve spectral resolution⁴⁷ so that coupling between indirectly bonded C–H pairs could be observed. A sample that has a chiral fluorinated solute dissolved in a liquid crystal was used to carry out a 2D ^{19}F spin echo⁴⁷ experiment in conjunction with the near magic angle spinning. This allows spectral analysis of small molecules to give residual dipolar coupling D_{ij} between nuclei i and j , and the isotropic spin–spin coupling J_{ij} . A deuteron 2D spin echo experiment on PAA- d_{14} allows assignment¹⁹ of quadrupolar splittings in the NMR spectrum of perdeuterated p -azoxyanisole. The same technique has been used in the nematic phase of β -deuterated 5CB dispersed in polymers⁴⁸ and in model bilayer membranes⁴⁹ to determine the homogeneous linewidth of the individual lines. Another form of deuteron 2D experiment is 2D exchange spectroscopy,^{50–52} which is capable of detecting slow molecular processes by monitoring the orientation of a C–D bond via its NMR frequency. A typical 2D time domain spectroscopy experiment involves four distinct periods [preparation, evolution (t_1), mixing, and detection (t_2)], leading to a time domain signal $s(t_1, t_2)$. Fourier transform of $s(t_1, t_2)$ gives $s(\omega_1, \omega_2)$, a 2D frequency spectrum. The

Figure 7 Experimental (left) and simulated (right) spectra for (a) PS3 and (b) PS6 taken at 250 K with a mixing time of 100 ms. Contour plots are shown as insets⁵²

spectrum provides information relating the frequency ω_e in the evolution period just before mixing and the frequency ω_d in the detection period just after mixing. When ω_e is identical to ω_d , this gives rise to a spectrum on the diagonal of a 2D spectrum; otherwise, off-diagonal intensity can be formed in the form of straight ridges and ellipses.^{50,52} The detection of off-diagonal intensity is practical for motions that have a correlation time of the order of milliseconds or longer. As an example, deuteron 2D exchange spectroscopy in glass-forming liquid crystalline side-group polymers is described.⁵² Figure 7 shows the experimental and simulated 2D spectra for poly(4-alkyloxybenzoic acid 4'-methoxyphenyl- d_4 ester)siloxane (PS n) with $n = 3$ and 6. Both PS3 and PS6 were magnetoaligned in a strong magnetic field by slow cooling from the isotropic melt into the glassy state. The glassy state of the PS6 is a frozen smectic C phase, while the glassy state of the PS3 is a frozen nematic phase. Off-diagonal intensity in the form of a partial elliptical pattern can be simulated by assuming a Gaussian distribution for the orientation distribution of the long axis of the mesogenic unit. Because the orientational order $\langle P_2 \rangle$ of PS3 is lower, the partial elliptical pattern is more pronounced for PS3 than for PS6 as seen in Figure 7. It was also found that the ring flip of 180° in PS n has a rather narrow angular distribution. The same technique has been used to study molecular dynamics in glass-forming discotic liquid crystals.⁸

1 INTRODUCTION

The NMR methods involving pulsed magnetic field gradients provide one of the most attractive techniques for studies of molecular transport in lipid membranes and lyotropic liquid crystalline systems. One of the most successful applications of pulsed field gradient (PFG) NMR is found in the field of complex liquids. In particular, this has been an invaluable tool in determining the structures of cubic liquid crystalline phases.¹ Almost two decades ago, the first lateral diffusion coefficient of an amphiphile in a lamellar liquid crystalline phase was measured directly with the PFG NMR method.² In recent years, the range of applications of NMR diffusion techniques has been growing rapidly, due to the great improvements in the NMR equipment for diffusion and NMR microscopy.³ We concentrate here on lyotropic liquid crystalline systems (Figure 1) containing membrane lipids or other amphiphilic molecules.

2 NMR MEASUREMENTS OF LIPID LATERAL DIFFUSION IN ORIENTED BILAYERS

The translational motion of lipids can be measured using the conventional NMR diffusion pulsed field gradient spin echo (PFG-SE) method for anisotropic liquid crystalline systems, if all static proton dipole–dipole interactions can be removed by some mechanical method. For studies of the lateral diffusion of lipids in a lamellar phase the removal of these interactions can be accomplished by a macroscopic alignment of the lamellae between, for example, glass plates.^{2,4,5} In lipid bilayers, provided that the translational diffusion rapidly leads to a zero average of all the static, intermolecular dipolar interactions, the dipolar Hamiltonian $\hat{\mathcal{H}}_D$ can be written^{6,7}

$$\hat{\mathcal{H}}_D = \sum_{i>j} \sum_p F_0^{(2)}(ij) D_{p0}^{(2)}(\Omega) \hat{A}_p^{(2)}(ij) \quad (1)$$

where

$$F_0^{(2)}(ij) = 2\gamma^2 r_{ij}^3 \overline{D_{00}^{(2)}(\Omega_{ij})} \quad (2)$$

where γ is the magnetogyric ratio, r_{ij} is the distance between the protons in an intramolecular proton pair ij , Ω_{ij} is the Eulerian angle between the proton–proton vector and the bilayer normal (the so-called ‘director’), and $\overline{D_{00}^{(2)}(\Omega_{ij})}$ is a Wigner rotation matrix element.⁸ The bar indicates averaging over all the fast motions. Likewise, $D_{p0}^{(2)}(\Omega)$ is a rotation matrix element, and Ω is the Eulerian angle between the bilayer director and the applied magnetic field $\mathbf{B}_0$. $\hat{A}_p^{(2)}(ij)$ is a component of an irreducible tensor operator of rank two operating on the nuclear spin coordinates. In a strong magnetic field only the term containing $\hat{A}_0^{(2)}(ij)$ affects the spectrum. $\hat{\mathcal{H}}_D$ for all the protons in the hydrocarbon chain can then be written

$$\hat{\mathcal{H}}_D = \frac{1}{2}(3 \cos^2 \theta - 1) \sum_{i>j} F_0^{(2)}(ij) \hat{A}_0^{(2)}(ij) \quad (3)$$

From equation (3) it is obvious that if the bilayer is macroscopically aligned and oriented at the so-called magic angle $\theta = 54.7^\circ$, then $\hat{\mathcal{H}}_D = 0$ and the static dipolar couplings are reduced. In the NMR experiment the diffusion is measured in the direction of the magnetic field gradient. For a lipid membrane or a lamellar phase the diffusion coefficient is orientation dependent and two constants D_L and $D_\perp$ describe the diffusion. D_L is the lateral diffusion coefficient for motion parallel with the membrane, and $D_\perp$ determines the diffusion perpendicular to the bilayer. The measured diffusion coefficient D for an oriented membrane system is then

$$D = D_L \sin^2 \theta + D_\perp \cos^2 \theta \quad (4)$$

for a lamellae oriented at the magic angle $\sin^2 \theta = \frac{2}{3}$. In lipid bilayers, $D_\perp$ should be orders of magnitude smaller than D_L and the second term in equation (4) can be neglected.

Early on, this method was used to determine the lateral diffusion coefficient of a phosphatidylcholine lipid in a lamellar phase^{2,4} and for potassium oleate⁵ (Table 1). One of the most annoying difficulties one was faced with in the first measurements of the lateral diffusion coefficient of lipids was the contribution from water protons to the spin echo signal, which results in a diffusion coefficient for the lipids which is too large. This problem can be solved by a careful exchange of all free protons for deuterium. For example, the lateral diffusion coefficient of a typical amphiphile-like sodium octanoate (C_7COONa) was measured² to be equal to $2.1 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ at 24°C .

The lateral diffusion coefficient is also affected⁹ by a change in the water content in the lamellar phase (Table 1). It was found that the lateral diffusion of dipalmitoylphosphatidylcholine (DPPC) increased by a factor of 2 for a change in the $^2\text{H}_2\text{O}$ content of 15 to 40 wt.%. Wu and Huang¹⁰ have calculated the change in the lateral diffusion as a function of the water content according to the theory of Brownian motion in thin sheets. They found that the dependence of phospholipid diffusion on hydration can be attributed primarily to the change in the bulk water mobility in the multilamellar phase.

Figure 1 Structure of the most common liquid crystalline phases that membrane lipids can form: (H_I) normal hexagonal phase; (L_α) lamellar phase; and (H_{II}) reversed hexagonal phase.⁹⁸ (I_I) A scaled model of a unit cell of a cubic phase structure built up of closed micelles.⁸³ (I_{II}) Schematic drawing of a bicontinuous cubic phase belonging to the space group $Im3m$ ¹

Recently, we reported on the effect of glycerol on the translational and rotational motions in aqueous lipid bilayers.¹¹ A continuous decrease in the lipid diffusion coefficient was observed upon increasing glycerol contents; thus, at room temperature $D = 12.6 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$ for an aqueous L_α phase, while $D = 1.9 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$ where all the water was displaced by glycerol. It was concluded that glycerol between the lipid bilayers affects the lipid diffusion due to changes in the viscosity in the interbilayer regions. This is also in accordance with the findings of Wu and Huang.¹⁰

As intuitively expected, the lateral diffusion coefficient depends on the hydrocarbon chain length, but the dependence is rather weak.^{2,9} On the other hand, a strong dependence on the translational motion is observed for different polar headgroups of the amphiphiles.² Thus, lysophosphatidylcholine (lyso-PC) diffuses somewhat more slowly than the corresponding PC, although the latter has two acyl chains and the lyso compound only one.^{12,13} The bulkier headgroup of the lyso-PC molecules most probably plays an important role for the lipid lateral diffusion. In studies^{14,15} of the lateral diffusion of the two dominant glucolipids in the bacterium *Acholeplasma laidlawii* it was found that the translational motion of dioleoyldiglucoacylglycerol (DGLcDAG) is about 10 times faster than it is in dioleoyl-PC (DOPC)¹⁶ (Table 1). This difference in the lateral diffusion coefficients can probably be ascribed to differences in the interactions in the polar headgroup region and the packing of the lipids in the bilayer.^{2,15} Addition of a monoglucolipid results¹⁴ in a decrease in the lipid lateral diffusion, which has been suggested to be due to hydrogen bonding between the polar headgroups.¹⁵ The theoretical models used in molecular dynamics simulations of the

lateral diffusion in lipid bilayers disregard the effect on the polar headgroup, and therefore the calculated diffusion coefficients are much larger than the measured ones. A value of the diffusion coefficient which is about an order of magnitude (or even more) too large is obtained.^{17–19} The reason for this discrepancy is that headgroup–headgroup interactions are essential for slowing down the diffusion process.

The effects of cholesterol on lipid membranes have been studied extensively with a number of spectroscopic methods. Cholesterol has been shown to have a condensing effect on many lipids in the lamellar phase, but it was not until recently that the ternary phase diagram of DPPC/cholesterol/water was presented.²⁰ As the cholesterol content in the lipid bilayer increases, two lamellar phases with different molecular ordering are formed. This unusual behavior has been explained by a theoretical model.²¹ The influence of cholesterol on the lipid lateral diffusion in various lamellar liquid crystalline phases has also been investigated (Table 1) by PFG NMR.^{9,16} ¹H NMR and bandshape simulations of phospholipid/water systems show that the addition of cholesterol to lipid bilayers in the gel phase induces a ‘super-Lorentzian’ ¹H NMR bandshape, which is a result of an enhanced lateral diffusion of the PC molecules.²² It can be inferred from Table 1 that the cholesterol concentration has a very small effect on the phospholipid diffusion in unsaturated lipid bilayers. This is in accordance with recent molecular dynamics simulations, where it was found that cholesterol does not have any significant effect on the lateral diffusion of the chains.¹⁸ On the other hand, cholesterol has a large influence on the molecular ordering in bilayers.^{16,23–25} Thus, cholesterol increases the molecular ordering in a bilayer, but the diffusional motion

is unaffected. In a study¹³ of the lipid lateral diffusion of a mixture of DOPC, dioleoylphosphatidylethanolamine (DOPE), and water, both lipids were found to have about the same D_L (5×10^{-12} m² s⁻¹) as DOPC bilayers.¹⁶

The diffusional motion for powder samples of a liquid crystalline phase have also been measured.^{26–28} To reduce the static dipole interactions, a combined multiple pulse homonuclear decoupling and multiple pulse gradient technique²⁶ has been used to determine the self-diffusion coefficient. By this method the diffusion of DPPC has been studied at 25 °C with 15 wt.% ²H₂O in the $L_{\beta'}$ gel phase and in the lamellar phase of potassium oleate in 30 wt.% ²H₂O. The D values obtained in this way are 1.6×10^{-14} and 1.3×10^{-12} m² s⁻¹, respectively. Here the lateral diffusion coefficient is not obtained directly,²⁹ but is some kind of an average value, since the microcrystallites in the mesophase are randomly oriented. In

such a measurement, the diffusion coefficient obtained is too small, compared with the local lateral diffusion. In an early study, Roberts²⁷ used the stimulated echo to determine the surfactant diffusion in the hexagonal and lamellar phases of potassium laurate/heavy water at 80 °C. Somewhat surprisingly he obtained a similar diffusion coefficient ($D_{\text{lamellar}} = 2.4 \times 10^{-10}$ m² s⁻¹ and $D_{\text{hexagonal}} = 2.3 \times 10^{-10}$ m² s⁻¹) for both phases, although there is a large difference in their structure.

By using pulsed field gradient double quantum spin echo decays the translational diffusion of dichloromethane dissolved in two thermotropic liquid crystals has been studied.³⁰ Diffusion constants of the solute were determined parallel and perpendicular to the magnetic field.

A method has been presented for simulating ³¹P NMR spectra from a lipid vesicle dispersion. Experimental spectra are obtained by the use of a DANTE pulse sequence.³¹ The

simulation was based on molecules with axially symmetric lineshapes undergoing lateral diffusion on a curved surface. By fitting a set of spectra for which the system is allowed to evolve for a variable time interval after the DANTE excitation, a lateral diffusion coefficient can be calculated from the measured correlation time. Köchy and Bayerl³² measured ^2H quadrupolar transverse relaxation times obtained with the Carr–Purcell–Meiboom–Gill (CPMG) pulse sequence on spherical phospholipid bilayers on a solid support. They took advantage of the fact that the CPMG sequence can progressively filter out contributions to the T_2 relaxation arising from motions, such as lateral diffusion, which are slow on the NMR timescale. For POPC supported bilayers they got $D = 4 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$ at 30°C , in good agreement with PFG NMR.¹⁶ An attempt to estimate the lipid lateral diffusion in phospholipid vesicles from ^{13}C spin–spin relaxation was less successful.³³ The authors used a very simple model to describe the spin relaxation, a model which is similar to the so-called ‘two-step model’.^{34–36} The lateral diffusion coefficient required to fit the values of T_2 is larger by almost two orders of magnitude than the values obtained with PFG NMR.

3 NMR MEASUREMENTS OF WATER AND ION DIFFUSION IN LIQUID CRYSTALS

Most of the investigations of water diffusion in lyotropic liquid crystalline systems have been conducted on powder samples. The intermolecular exchange of protons in the water molecule is rapid on the NMR timescale, and therefore the water signal is relatively sharp even for a nonoriented sample. When the diffusion coefficient is determined for a powder sample with the NMR technique, the resulting echo has contributions from lamellae of all orientations θ , and²⁹

$$S(t) = \int_{-1}^1 \exp \left\{ -\frac{2\tau}{T_2(\theta)} - \sin^2 \theta (\gamma g \delta)^2 D (\Delta - \delta/3) \right\} d \cos \theta \quad (5)$$

The first measurements of water diffusion coefficients in lamellar phases of a powder sample were performed by Blinc and co-workers.³⁷ However, the complications described by equation (5) were not considered in their determination of the water diffusion at different temperatures for a sample containing 70% sodium palmitate and 30% water. Assuming that the water molecules in lamellae oriented close to the magic angle make the major contribution to the spin echo, the measured diffusion coefficient should be multiplied²⁹ by $\frac{3}{2}$ to give $D_L = 8 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$. Water diffusion coefficients have, however, also been determined for oriented lamellar phases using both protons³⁸ and deuterium³⁹ pulsed field gradient NMR. Callaghan and co-workers³⁹ found that the diffusion coefficients of $^2\text{H}_2\text{O}$ parallel and perpendicular to the bilayer surface are $D_L = 1.7 \times 10^{-9}$ and $D_\perp = 5 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$. In this work they also reported the first solid echo PFG ^2H NMR experiment performed on a lamellar phase of potassium palmitate and water in the presence of quadrupole splittings.

In the lithium perfluorooctanoate/water system, self-diffusion coefficients are reported for water, lithium and perfluorooctanoate ions in the lamellar and viscous neat phases, as a function of temperature.³⁸ The difference between diffusion along the water layers and across the perfluorooctanoate bilayers was found to be small for both water and lithium ions.

The lithium ion diffusion coefficient was only a factor of 3 larger than that of the perfluorooctanoate amphiphile. The lithium diffusion coefficient has also been determined in a lamellar phase composed of octanoate, water and decanol.⁴⁰ It was found that the lithium ion diffusion in this lamellar phase is independent of the composition. This is due to a constant fraction of bound ions in accordance with the ion condensation model previously used to describe the ion binding in lyotropic liquid crystals.^{41,42} Recently, the PFG method was applied to estimate the rates of ionophore-mediated transmembrane exchange of lithium ion in liposomes.⁴³ There was good agreement between the transmembrane exchange rate estimated from PFG and magnetization transfer ^7Li NMR experiments.

Water diffusion coefficients have been measured for powder samples in the two-component system of DPPC and water.²⁹ The diffusion coefficients were found to be 4–10 times smaller than the translational diffusion coefficient in bulk water, and essentially unaffected by changes in the phase structure.

Some recent investigations of the effect of the mesophase structure on the measured water diffusion coefficients have also been published.^{44,47}

4 LIPID LATERAL DIFFUSION IN CUBIC LIQUID CRYSTALLINE PHASES

Lipid translational diffusion coefficients have been determined for a large number of different lyotropic cubic phases (Table 2). There is a great deal of interest in the structure and the properties of membrane lipids, in particular the cubic and reversed hexagonal phases, since these lipid phase structures are believed to be involved in many biologically important membrane processes such as fusion^{48–50} and membrane lipid regulation.^{1,15,51–53} With X-ray diffraction methods^{54–57} the space group of the cubic structure can usually be obtained, but seldom is it possible to distinguish a bicontinuous structure from a structure consisting of closed micellar aggregates. The strength of the PFG NMR method is that it can discriminate between these two structures, since restricted motions in space can be easily observed.⁵⁸ The first PFG NMR study of amphiphile diffusion in a cubic phase was carried out by Charvolin and Rigny⁵⁹ for a soap system of potassium laurate which formed a cubic phase at 80°C ($D = 2 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$). Such a large diffusion coefficient is not compatible with closed aggregates. Conclusions about whether or not a cubic phase consists of closed aggregates are based on a comparison between lipid diffusion coefficients measured by PFG NMR for neighboring phases, with which the cubic phase is in equilibrium.^{2,4,60,61}

The apparent diffusion coefficients of cubic and lamellar phases can be qualitatively compared with a simple model.^{2,61,62} The restricted lipid diffusion within aggregates building up the cubic lattice can be described by a local diffusion tensor, $\mathbf{D}$, where the component representing restricted diffusion in a certain direction is set to zero. The measured diffusion coefficient D is then an average value of the local diffusion tensor:

$$D = \frac{1}{3} \overline{\text{Tr} \mathbf{D}} \quad (6)$$

where the bar denotes an average over all the sites in a unit cell of the liquid crystal. Depending on how many directions

are effectively available for the lipid diffusion as measured by PFG NMR, three possibilities can be distinguished:

1. For a cubic phase with closed micelles, the lipid diffusion is restricted in all three directions, all the diagonal elements in the tensor are equal to zero, and D is ideally equal to zero.
2. A cubic structure of connected, long, rod-like aggregates permits lipid diffusion in one direction (along the rod) with the diffusion coefficient $D_{\parallel}$, and

$$D = \frac{1}{3} \overline{\text{Tr} \mathbf{D}_{\text{rod}}} = \frac{1}{3} D_{\parallel} \quad (7)$$

3. For a cubic phase with bilayer units, the diffusion $D_{\text{L}}^{\text{cub}}$ can occur in two directions, and

$$D = \frac{2}{3} D_{\text{L}}^{\text{cub}} \quad (8)$$

Thus, it can be expected that the aggregate structure in the cubic phase will appreciably influence the magnitude of the measured diffusion coefficients. In particular, PFG NMR provides a convenient method for distinguishing between bicontinuous cubic phases and those having closed aggregates. According to the above equations it should also be possible to obtain a crude estimate of the geometry of the aggregates building up the cubic phase, by comparing diffusion coefficients of lipids in the lamellar and cubic phases. Such a comparison

assumes that the local environment of the molecules in the diffusing process is the same in the two phases.

For the comparison of diffusion coefficients of lipids and water in cubic phases, an attractive mathematical model based on a description of the cubic structure by periodic minimal surfaces can be used.^{1,63–66} Recently, Anderson and Wennerström⁶⁶ have presented numerical results for the geometric obstruction factor of self-diffusion in different bicontinuous, cubic microstructures. The lipid diffusion was modeled as a diffusion of a particle, confined to the polar–apolar dividing surface, with a constant diffusion coefficient D_0 . It was proven analytically that the effective diffusion coefficient for a particle diffusing over any minimal surface of cubic symmetry is exactly equal to $\frac{2}{3} D_0$.

4.1 Bicontinuous Cubic Phases

The most widely investigated bicontinuous cubic phases occur in the monooleoylglycerol (MO)/water system. An early X-ray diffraction and PFG NMR investigation of the lipids and water in this system suggested that the cubic phase structure was based on lamellar bilayer units.⁶² The simple model described above was applied. The results of the MO system were compared with those of the aerosol OT/water system. The cubic phase of the latter system was suggested to be built up of rod-like aggregates. Using equations (7) and (8), surprisingly good predictions were made of the aggregate shape in the cubic phases.

Table 3 Water and Lipid Diffusion in Cubic Phases of Monooleoylglycerol and Water⁷²

¹ H ₂ O ^a (wt.%)	Phase	$D_{\text{cub}}^{\text{water}}/D_0^{\text{b}}$	$D_{\text{cub}}^{\text{lipid}} \times 10^{12} (\text{m}^2\text{s}^{-1})$	p_b	n
28.0	<i>Ia3d</i>	0.201	14.4	0.56	4.3

39.5	<i>Pn3m</i>	0.300	1.69	0.38	5.0

^a25 °C.^bMeasured water diffusion coefficient relative to that of pure water (see text).

The cubic phases of several monoglycerides exist over an extended water and temperature region in the phase diagrams.⁶⁷ These phases can dissolve substantial amounts of hydrophobic and amphiphilic molecules,^{68–71} as well as glycerol.¹¹ The relationship between the water diffusion coefficient in cubic phases and the MO and water contents has been investigated. The water diffusion coefficient $D_{\text{cub}}^{\text{water}}$ in a simple two-site model can be written⁷²

$$D_{\text{cub}}^{\text{water}} = p_b D_{\text{cub}}^{\text{lipid}} + (1 - p_b) \beta D_0 \quad (9)$$

where p_b is the fraction of bound water, $D_{\text{cub}}^{\text{lipid}}$ is the lipid diffusion coefficient in the cubic phase, β is the obstruction factor for the diffusion of unbound water in the cubic phase, and D_0 is the diffusion of bulk water. The association of water obtained from the application of this simple model (Table 3) should be taken as a quantification of the extent to which the surface of the aggregates affects the dynamic properties of water. The diffusion coefficient of water⁷² has a discontinuous increase at around 34% water, which harmonizes with the two-phase region between the *Ia3d* and *Pn3m* cubic structures.⁷³ The lipid diffusion was found to increase with increasing unsaturation of the acyl chains of the lipid, and it decreases when larger molecules such as cholesterol, gramicidin A, and lysooleoyl-PC are solubilized in the cubic phase. In a cubic liquid crystal of MO, DOPC, and water, the individual lipid diffusion coefficients can be determined simultaneously. The results obtained suggest that when probe techniques are used the choice of the probe itself may influence the measured lipid diffusion coefficient. Recently, we investigated the cubic phase of *N,N*-dimethyldodecylammonium oxide (DDAO) having a molar ratio of 97:3 between DDAO and gramicidin and 27 wt.% water. At 25 °C, and taking the diffusion coefficient of water as $D_{\text{water}} = 6.3 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$, the measured diffusion coefficients for the methyl groups of the polar headgroup and the terminal methyl group were $7 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$. The latter coefficient should be compared with the coefficient for the diffusion of DDAO in a cubic phase in the absence of gramicidin; the value is $10 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$, i.e. gramicidin causes quite a small obstruction effect.

Several membrane lipid–water systems give rise to freeze–fracture replicas of three-dimensional regular arrays of closely packed globular elements, often called ‘lipidic particles’.⁷⁴ These structural pictures have often been poorly classified, and they have been suggested to show closed lipid aggregates, such as reversed micelles. Investigations of some liquid crystalline phases, giving rise to the freeze–fractured replicas, with X-ray diffraction and PFG NMR indicate that they are: (1) cubic liquid-crystalline phases; and (2), with one

exception, bicontinuous cubic phases.¹³ There is a rather large accumulation of diffusion coefficients to verify the structure of bicontinuous cubic phases (Table 2).^{2,12,14,15,28,53,61,75–80}

4.2 Discontinuous Cubic Phases

Usually these cubic structures are located between the micellar solution and the H_I phase in the phase diagram.⁸¹ X-Ray diffraction showed that this structure belongs to the space group *P43n* or *Pm3n*. For a long time it was debated whether the structure consists of closed aggregates^{12,60,75,82–84} or of a network of connected rod-like micelles with enclosed spherical micelles.^{55,85} This debate is now settled,^{86,87} and it has been shown conclusively by PFG NMR (Table 2)^{83,84,88} that this cubic structure is discontinuous. From NMR lineshapes,⁸³ spin relaxation,^{89,90} and time-resolved quenched fluorescence^{84,91} it is concluded that the structure consists of slightly elongated, closed micelles (Figure 1). Recently, a cubic phase consisting of reversed micelles was established.⁹² The structure of this phase, which belongs to the space group *Fd3m*, and which is composed of DOPC and dioleoylglycerol or oleic acid and sodium oleate, was recently solved by means of low-resolution crystallography.⁹³ The structure consists of a complex packing of two types of quasi-spherical reversed micelles. PFG NMR has shown⁹⁴ for the cubic phase composed of DOPC and dioleoylglycerol that reversed micelles build up the structure. The diffusion coefficient of DOPC is very small, close to $10^{-13} \text{ m}^2 \text{ s}^{-1}$, while the diffusion of water and dioleoylglycerol are much more rapid [of the order of $10^{-11} \text{ m}^2 \text{ s}^{-1}$ (Figure 2)]. It was concluded⁹⁴ that the reversed micelles contain mainly DOPC and the dioleoylglycerol merely plays the role of a solvent.

5 LATERAL DIFFUSION IN OTHER NONLAMELLAR LIQUID CRYSTALS

The translational diffusion of all three components has been measured in the ternary system DOPC/water/dodecane,⁷⁸ where dodecane induces an H_{II} phase. From a comparison between diffusion coefficients, it was concluded that dodecane resides between the water cylinders in the H_{II} phase.

Some lyotropic mesophases, called ‘nematics’, orient spontaneously in a strong magnetic field. Utilizing ultraviolet (UV) linear dichroism on a solubilized chromophore and PFG NMR on a nematic phase containing potassium dodecanoate, it was shown that this phase is built up of long rod-like micelles.^{95,96}

Figure 2 Stacked plot of spectra with increasing strength of the pulsed field gradient in a diffusion experiment performed on the system DOPC/1,2-dioleoylglycerol/ $^2\text{H}_2\text{O}$ (25.44/59.57/14.99) at 42 °C. The two peaks marked in the figure correspond to (A) CH_3 groups of the choline headgroup, and (B) terminal CH_3 groups of DOPC and 1,2-dioleoylglycerol. The diffusion coefficient of A is estimated to be $3 \times 10^{-13} \text{ m}^2 \text{ s}^{-1}$, while B shows two diffusion coefficients of 0.3×10^{-12} and $15 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$

The translational diffusion coefficient of the amphiphile was obtained from an aligned sample oriented at the magic angle. The surfactant diffusion along the rod was found to be $D_L = 5 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$ for potassium laurate and $D_L = 8 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$ for sodium decyl sulfate.⁹⁶ These values compare well with the lateral diffusion coefficients for the corresponding lamellar mesophases (Table 1). By means of the relationship $\langle x^2 \rangle = 2Dt$, the length can be estimated to be longer than 2000 nm.

1 INTRODUCTION

In the liquid state, spin relaxation is caused by the random fluctuations of magnetic interactions resulting from Brownian rotational and translational diffusion of molecules, conformational transitions, or solvation effects. These motions act as random time-dependent perturbations, which induce transitions among the spin states and ultimately lead to Boltzmann equilibrium values of macroscopic magnetization vector components, altered by application of the excitation field in relaxation experiments. Random magnetic perturbations are characterized by the equilibrium average $\overline{\Delta}$, the mean-square value $\overline{\Delta^2}$, and the persistence or correlation time τ . It is convenient to express Δ in frequency units rather than in energy units; the strength of the interaction is therefore divided by the Planck constant $\hbar$.

In high-resolution NMR spectroscopy, a fast motional regime, characterized by the condition $(\Delta^2 - \overline{\Delta^2})\tau^2 \ll 1$, often holds. This situation is the simplest to analyze by time-dependent perturbation theories and is generally referred to as the Redfield limit.¹ In this condition, both the longitudinal component of the macroscopic magnetization along the static field $\mathbf{B}_0$, and the transverse component created by the observing field $\mathbf{B}_1$, relax as simple exponentials, with characteristic times T_1 and T_2 , respectively. The theoretical expressions predicted by the theory for T_1^{-1} and T_2^{-1} are very simple and the relaxation times come out to be of the order of $(\Delta^2 - \overline{\Delta^2})\tau$. Thus, if the dominant relaxation mechanism is provided by modulation due to rotational diffusion of an intramolecular interaction described by an axially symmetric second-rank tensor $\mathbf{T}$ with principal components $T_{zz} = T_{\parallel}$ and $T_{xx} = T_{yy} = T_{\perp}$, spin relaxation times of the order of 1 s will result for $\Delta = T_{\parallel} - T_{\perp} = 10^5 \text{ s}^{-1}$ (a value appropriate for the ^{13}C -H spin dipole interaction) and $\tau = 10^{-10} \text{ s}$, corresponding to the rotational correlation time of most liquids under normal conditions.

The motional processes responsible for spin relaxation in liquids are almost invariably interpreted in terms of diffusion models, so that a few comments on the underlying theoretical treatments are in order. A diffusional regime for molecular translations and rotations applies when strong impulsive interactions with the surrounding molecules interrupt the inertial motion of the particle so frequently that a random walk of infinitesimally short steps actually results. To interpret

these dynamic processes, an equation of motion for the test particle can be set up, including a dissipative term in the form of a frictional force. In fact, the resulting equation is the basis of the method for describing molecular motions in fluids known as 'Brownian dynamics'.² (see *Brownian Motion and Correlation Times*.)

Alternatively, a stochastic equation can be derived to interpret the time evolution of the probability distribution function specifying molecular coordinates. The treatment leading to this equation, often referred to as the 'diffusion (or Smoluchowski) equation' when inertial effects are completely quenched, is reported in specialized texts.³ (We reserve the term 'Fokker-Planck equation' for the more general formalism which takes into account translational and angular velocity of the particle, in addition to translational and angular coordinates. According to this description, the diffusional behavior is recovered if velocities are quenched within a time shorter than the decay time for the spatial variables.) The diffusion equation is a differential equation formally similar to a time-dependent Schrödinger equation and it can be solved by similar methods. In fact, after separating the time variable, the solution of the resulting second-order differential equation is reduced to the determination of eigenvalues and eigenvectors of the matrix representation of the diffusion operator on a suitable set of functions. The mathematical details are given elsewhere,^{4,5} so we give here only the relevant physical factors in the diffusion equation. These are:

1. The potential function arising from forces and torques exerted on the test particle, including terms accounting for hindered internal motions.
2. Diffusion coefficients (or, more generally, diffusion tensors) which take into account frictional effects. Diffusion coefficients are determined by the molecular geometry and viscosity of the medium by the Stokes-Einstein relationships.^{6,7}

The general considerations given above hold for both isotropic and anisotropic liquid phases. We will see in the following discussion how the specific nature of the liquid crystal environment may not only alter the characteristics of dynamic processes that occur in normal liquids (e.g. features of rotational and translational diffusion, or static and dynamic parameters of conformational changes), but also introduce novel relaxation mechanisms which are absent in isotropic fluids.

2 EXPERIMENTAL OBSERVABLES

NMR relaxation experiments in liquid crystals can be performed both on the molecules forming the mesophase and on solutes suitably chosen to probe the dynamic properties of the environment. Under normal experimental conditions, fast motional regimes hold, providing well-resolved spectra. Measurements on specific nuclear positions of the molecule can therefore be performed to give data which can then be processed theoretically in order to extract dynamic information. For this reason, ^{13}C (either in natural abundance or chemically enriched) and ^2H (introduced by specific deuteration) are the favored nuclei for use in relaxation experiments on liquid crystals. For ^{13}C and ^2H nuclear spins, the dominant source of spin relaxation is provided by the ^{13}C -H dipole and ^2H quadrupole interactions, respectively. With the very high fields used in modern spectrometers, shielding anisotropies may also have

relevant effects. In all cases, these interactions are described by second-rank Cartesian tensors.

According to the Redfield theory (see *Relaxation Theory: Density Matrix Formulation*), the equations for ^{13}C (under proton decoupling) and ^2H longitudinal relaxation times are

$$1/T_1^{\text{C}} = (\frac{1}{12})[J_0(\omega_{\text{H}} - \omega_{\text{C}}) + 3J_1(\omega_{\text{C}}) + 6J_2(\omega_{\text{H}} + \omega_{\text{C}})] \quad (1)$$

and

$$1/T_1^{\text{D}} = (\frac{1}{4})[J_1(\omega_{\text{D}}) + 4J_2(2\omega_{\text{D}})] \quad (2)$$

where $J_p(\omega)$ are spectral densities, i.e. the Fourier transforms (FTs) of the correlation functions describing the time evolution of the irreducible spherical components⁸ of the second-rank magnetic interactions in a laboratory reference frame. In fact, the magnetic tensor components are defined in a molecular axis system, and therefore appear to vary in time when viewed from the laboratory system, because of molecular tumbling in the liquid. The FTs are calculated at frequency values related to ^1H , ^{13}C , and ^2H resonance frequencies in the experiment. Spectral densities can be expressed in terms of the magnitude of the interactions, and of the time decay of angular functions (Wigner rotation matrix components⁸) which define the molecular orientation with respect to the laboratory fixed reference frame. The FT $j(\omega)$ of an exponential function characterized by time constant τ is

$$j(\omega) = \frac{\tau}{1 + \omega^2\tau^2} \quad (3)$$

Complete dynamic information on a system should be achieved by relaxation experiments capable of providing the various spectral densities at different frequencies. Modern experiments are actually performed at a number of working frequencies.^{9,10} It is also interesting to note that equations (1) and (2) refer to standard experiments of saturation or inversion–recovery of the total longitudinal component of magnetization. In this way, individual spectral densities cannot be obtained directly from experimental data. However, they can be provided by applying appropriate sequences of radiofrequency (rf) pulses to the spin system. Equations for relaxation rates determined by various pulse experiments on a single spin $I = 1$ in ordered phases are reported in Table 3 of Vold¹¹ (see also *Deuteron Relaxation Rates in Liquid Crystalline Samples: Experimental Methods*).

Experiments in liquid crystal phases are performed on samples which are macroscopically oriented by means of magnetic fields, surface effects or electric fields. In some instances, it is also possible to measure the angular dependence of the spectral densities when the axis of preferential alignment of the mesophase (the optical axis, or director) can be rotated away from the magnetic field direction. This can be easily done with uniaxial smectic-A phases. Again, explicit equations for the angular dependence of the spectral densities appropriate for this case may be found in Vold.¹¹

3 DYNAMIC MODELS

In a liquid sample at thermodynamic equilibrium, the dynamic processes which cause thermal motions of the

molecules are defined as random stationary. Although the system is macroscopically in equilibrium, the coordinates specifying the position and orientation of any molecule, here collectively denoted by $\mathbf{x}$, exhibit random walk in time. Any function of these coordinates will behave as a function $f[\mathbf{x}(t)]$ randomly varying in time. If a physical property of the system is related to the function $f(\mathbf{x})$, experimental measurements can be made to determine directly the equilibrium average:

$$\bar{f} = \int d\mathbf{x} f(\mathbf{x})P(\mathbf{x}) \quad (4)$$

thus providing information on equilibrium distribution $P(\mathbf{x})$.

The main result of the stochastic theories is that, for random-stationary processes, knowledge of the random events occurring at the molecular level is entirely contained in a statistical property called the correlation function of $f(\mathbf{x})$:

$$\overline{f^*(t)f(0)} = \iint d\mathbf{x} d\mathbf{x}_0 f^*(\mathbf{x})f(\mathbf{x}_0)P(\mathbf{x}, t; \mathbf{x}_0, 0) \quad (5)$$

where $P(\mathbf{x}, t; \mathbf{x}_0, 0)$ is the joint probability of finding the molecule in $\mathbf{x}_0$ at an arbitrary initial time $t_0 = 0$, and in $\mathbf{x}$ at the later time t . It follows from the properties of the joint probability that this function becomes equal to $P(\mathbf{x})\delta(\mathbf{x} - \mathbf{x}_0)$ at time zero and to the product $P(\mathbf{x})P(\mathbf{x}_0)$ at infinite time, when correlation can no longer exist. Therefore, the correlation function varies between limits $|\bar{f}^2|$ at $t = 0$ and $|\bar{f}|^2$ at $t \rightarrow \infty$. It is often convenient to define the correlation function $g(t)$ for the deviation of $f(t)$ from the equilibrium value $\bar{f}$, thus obtaining

$$g(t) = \overline{f^*(t)f(0)} - |\bar{f}|^2 \quad (6)$$

The mean square value $|\bar{f}^2|$ and average $\bar{f}$ can be calculated from the equilibrium distribution $P(\mathbf{x})$, but the time evolution of the joint probability function requires a mathematical model derived on the basis of a physically reasonable picture, and this is provided by solution of the diffusion equation.

The above considerations may immediately be applied to the problem of reorientational motions, which cause random fluctuations of the intramolecular anisotropic magnetic interactions, and are of particular importance for ^{13}C and ^2H spin relaxation in any liquid phase.

The irreducible spherical components of second-rank tensorial interactions $\mathbf{T}$, expressed in a laboratory frame having the Z axis parallel to the static magnetic field $\mathbf{B}_0$, are given by⁸

$$T_{\text{lab}}^{(2,p)} = \sum_q \mathcal{D}_{pq}^{2*}(\Omega) T_{\text{mol}}^{(2,q)} \quad (7)$$

where $T_{\text{mol}}^{(2,q)}$ are the components in a molecular frame and $\mathcal{D}_{pq}^{2*}(\Omega)$ are Wigner rotation matrix elements carrying the transformation from the laboratory system (X, Y, Z) to the molecular frame (x, y, z), described by the set of Euler angles $\Omega \equiv (\alpha, \beta, \gamma)$. The time dependence of the quantities $T_{\text{lab}}^{(2,p)}$ is contained in that of the Euler angles Ω , which change randomly in time as a consequence of rotational motions. The effective perturbation induced by modulation of the $\mathbf{T}$

tensor components is determined by the deviation from the equilibrium value:

$$\delta T_{\text{lab}}^{(2,p)}[\Omega(t)] = \sum_q \{ \mathcal{D}_{pq}^{2*}[\Omega(t)] - \overline{\mathcal{D}_{pq}^{2*}} \} T_{\text{mol}}^{(2,q)} \quad (8)$$

Of special interest, therefore, are the autocorrelation functions $g_{pq}(t)$ of the Wigner components $\mathcal{D}_{pq}^{2*}(\Omega)$, defined as

$$g_{pq}(t) = \overline{\mathcal{D}_{pq}^{2*}(t) \mathcal{D}_{pq}^2(0)} - |\overline{\mathcal{D}_{pq}^2}|^2 \quad (9)$$

the overbar now denoting an average over the orientational degrees of freedom. The time behavior of the correlation functions $g_{pq}(t)$ is determined by the reorientational process undergone by the molecules, and the thermal averages $\overline{\mathcal{D}_{pq}^2}$ are determined by the nature of the liquid phase.

The spectral densities $J_p(\omega)$ which appear in the equations for the spin relaxation rates are

$$\begin{aligned} J_p(\omega) &= \frac{1}{2} \int_{-\infty}^{\infty} dt e^{-i\omega t} \overline{\delta T_{\text{lab}}^{(2,p)*}(t) \delta T_{\text{lab}}^{(2,p)}(0)} \\ &= \sum_q |\overline{T_{\text{mol}}^{(2,q)}}|^2 j_{pq}(\omega) \end{aligned} \quad (10)$$

where $j_{pq}(\omega)$ are the FTs of the correlation functions $g_{pq}(t)$.

In the case of molecules with internal degrees of freedom, the additional transformation from a fixed molecular frame to a reference system located in each molecular moiety must be considered explicitly. For a tensorial interaction located in the i th unit, equation (7) is rewritten as

$$T_{i,\text{lab}}^{(2,p)} = \sum_{q,n} \mathcal{D}_{pn}^{2*}(\Omega) \mathcal{D}_{nq}^{2*}(\Omega_i) T_i^{(2,q)} \quad (11)$$

The complex expressions resulting for correlation functions and spectral densities are given by Ferrarini et al.^{12,13}

3.1 Rotational Diffusion

In isotropic media, i.e. in the case of a spherically symmetric orientational distribution, it follows from the orthogonality properties of the Wigner functions that

$$\overline{\mathcal{D}_{pq}^2} = 0, \quad |\overline{\mathcal{D}_{pq}^2}|^2 = \frac{1}{5} \quad (12)$$

and the solution of the diffusion equation for axially symmetric molecules characterized by the principal values $D_{\parallel}$ and $D_{\perp}$ of the diffusion tensor gives

$$g_{pq}(t) = \left(\frac{1}{5}\right) \exp(-t/\tau_{pq}) \quad (13)$$

$$1/\tau_{pq} = 6D_{\perp} + (D_{\parallel} - D_{\perp})q^2 \quad (14)$$

Since the orientational correlation time in equation (14) is independent of the index p , the spectral densities $J_p(\omega)$ all turn out to be identical.

In ordered phases, as a consequence of anisotropic interactions with the environment, the molecules are subjected to an effective orientational potential $U(\Omega)$ which, unlike the

isotropic case, determines the nonuniform equilibrium distribution of orientations.

As the diffusion model is appropriate for describing the rotational dynamics of molecules in a liquid of normal density and viscosity, it is also suitable for use for liquid crystals. However, the motion in this case is better termed ‘anisotropic’ rotational diffusion, because of the orientational torques exerted on the molecules.

In nematics, rod-like or disk-like molecules tend to orient the symmetry axis to the director, giving rise to calamitic or discotic nematic phases, respectively. The condition of axial symmetry for the phase implies free rotations around the laboratory Z axis, and therefore $\overline{\mathcal{D}_{pq}^2}$ must be zero for $p \neq 0$. Nematic phases are generally expected to be uniaxial, although biaxiality cannot in principle be excluded. If the molecules themselves are assumed to be uniaxial, rotations about the molecular z axis are unhindered and only terms with $q = 0$ remain. For uniaxial molecules in uniaxial phases, the only order parameter directly measured by NMR is $\overline{\mathcal{D}_{00}^2}$, which coincides with the Legendre polynomial $\overline{P}_2$.⁸ The simple Maier–Saupe form

$$U(\beta)/k_B T = -\lambda P_2(\cos \beta) \quad (15)$$

is appropriate for this particular case, β denoting the angle between the director and the molecular symmetry axis.

The potential of the mean torque acting in nematics has two important effects on the efficiency of rotational motions as a source of spin relaxation. First, the magnitude of time-dependent perturbation is reduced with respect to the isotropic case, as the angular functions $\mathcal{D}_{pq}^{2*}(\Omega)$ average now to non-zero values. Thermal averages $\overline{\mathcal{D}_{pq}^2}$ are called ‘order parameters’, because they measure the anisotropy of the orientational distribution. A second consequence of the orientational potential is to alter the features of rotational motion. Since the particles are preferentially oriented with the symmetry axis (assuming a uniaxially symmetric molecule) parallel to the director, motions can be roughly separated into fast fluctuations about the preferred orientation (with the characteristic frequencies expected to increase with the strength of the orienting field, according to the simple picture of motions in a potential well), essentially free rotations about the symmetry axis, and flippings of the long axis, which, being hindered by the orienting potential, become slower with increasing ordering. The latter motion, however, is a very important relaxation mechanism for vectorial properties, e.g. dielectric relaxation, but it is ineffective for second-rank tensorial properties. The decay of correlation functions $g_{pq}(t)$ can be calculated by solving a diffusion equation for the rotational degrees of freedom, in which the effect of the orienting potential is included.^{4,5} The full solution of the diffusion equation requires expansion on the basis of the Wigner functions $\mathcal{D}_{pq}^j(\Omega)$, which are eigensolutions of the diffusional problem for the isotropic case. Correlation functions $g_{pq}(t)$ can, in most cases, be approximated by single exponentials:

$$g_{pq}(t) = C_{pq} \exp(-\alpha_{pq} t) \quad (16)$$

with the preexponential factors C_{pq} and decay rate constants α_{pq} now being dependent on the order parameters $\overline{P}_2$ and

$\overline{P}_4$, in addition to the diffusion coefficients $D_\perp$ and $D_\parallel$. Particularly simple expressions are obtained by an asymptotic solution of the diffusion problem for very highly ordered systems; these are reported in Table 2 of Chap. 18 of Nordio and Segre⁴ in terms of the parameter $\delta = 1 - \overline{P}_2$, which is a measure of the deviation from perfect alignment. In the limiting case of very high ordering, the only important motion is free rotation about the molecular symmetry axis, the other motions being too rapid to produce any effective spin relaxation.

The considerations given here hold whenever uniaxial orientational order is present, such as in nematic and smectic-A phases. However, they are essentially correct also for cholesteric and smectic-C phases, because a uniaxial environment is experienced at the molecular level.

3.2 Rototranslational Couplings

In phases where both spatial and orientational order are set up, a reorientational process, which is peculiar to liquid crystal phases with spatial inhomogeneity and cannot occur in normal liquids, may result from the translational motions. We consider here the cases of smectic and cholesteric phases. In the former case, elongated molecules tend not only to orient parallel to each other, but also to organize themselves in parallel planes. In uniaxial smectic-A phases, the anisotropic potential acting on a rod-like molecule depends both on the spatial coordinate Z along the director, perpendicular to the smectic layers, and the angle β formed by the director and the molecular axis.^{5,14} Because of the particular form of the potential, usually referred to as the ‘McMillan potential’,^{15,16} the translational and rotational motions of the test molecule are coupled. Physically, a molecule traveling along the Z direction perpendicular to the smectic planes will be subjected to different orientational forces, and therefore the average value of any orientation-dependent interaction will be modulated by the translational motion. In fact, we expect that probe molecules in typical smectic systems are more oriented when surrounded by aromatic cores than when surrounded by aliphatic tails.

Modulation of intramolecular magnetic interactions by translational motion, in addition to that resulting from rotational motion, gives rise to a mechanism reminiscent of scalar relaxation of the first kind,¹⁷ and ultimately produces similar effects. A simple interpretation of this relaxation mechanism can be given in the following way. The translational motion of the molecules is strongly anisotropic, with free diffusion within layers, and hindered diffusion across them. Translations parallel to the layers do not cause spin relaxation, because the orientational order is essentially constant. Spin relaxation results, of course, from anisotropic rotational diffusion, as in nematics. Translations perpendicular to the layers, which explore regions of a different order, are hindered by the anisotropic potential, and could be described by a diffusion equation including the McMillan potential. However, this motion can be visualized as an activated random jump process, with a correlation time given by the mean time required for the molecule to travel across layers of spacing d . The correlation time for the jump process is d^2/D_T , where D_T is the diffusion coefficient for translations perpendicular to the smectic planes. The contribution to the spin-relaxation time is proportional to

$$(\overline{P}_{2\max} - \overline{P}_{2\min})^2 (d^2/D_T) \quad (17)$$

where $\overline{P}_{2\max} - \overline{P}_{2\min}$ is the range of order parameters along Z .

In cholesteric phases too, a novel relaxation mechanism may occur, in addition to those already present in nematics, as a consequence of coupling between rotations and translations.

A simple picture of a single-domain cholesteric phase is that of a nematic in which the director moves along a helical structure, the axis of which is always perpendicular to the director itself. It follows that translation along the helical axis induces rotation of a rod-like molecule, so as to keep the long molecular axis parallel to the director. This motion gives rise to an important contribution to spin relaxation¹⁸ by modulating the residual magnetic anisotropies left by local ordering. The correlation time for this process is the mean time required for the molecule to undergo angular displacement of the director by one radian; this time is of the order of $(p^2/4\pi^2 D_T)$, where p is the helical pitch and D_T the diffusion coefficient for translations perpendicular to the director.

3.3 Internal Motions

The rigid rotor model is only a rough approximation for the dynamics of mesogenic molecules. Actually, molecular flexibility appears to be an important requirement for the achievement of mesomorphic states. Thus, thermotropic liquid crystals are generally made up of aromatic groups linked to flexible chains. The length and the chemical structure of the chains are important in determining their transitional properties and the nature of their mesophases. Very mobile units also characterize the lyotropics, which are water dispersions of molecules with a polar headgroup attached to long aliphatic tails. These species can be organized into structures in which regions with different characteristics can be distinguished: strong interactions of an electrostatic nature maintain the polar headgroups in hydrophilic layers separate from the hydrophobic domains of the alkyl chains. At appropriate temperatures and water concentrations, these systems may undergo transition to liquid crystal phases of different kinds, with the common feature that the chains are well aligned despite the high fluidity of the phase.

The NMR relaxation technique on specifically deuterated molecules was recognized early on as an essential tool in monitoring chain mobility, so that a large amount of experimental data is available. The timescales characterizing bond rotations depend on the specific molecule, but in most cases they range between 10^{-10} and 10^{-8} s. This means that internal motion must be an effective NMR relaxation mechanism, competing with the overall rotation of the molecule.

In the case of mesogenic molecules having a number of torsional degrees of freedom, collectively denoted by φ , the total potential undergone in the oriented phase is

$$U(\Omega, \varphi) = U^{\text{tors}}(\varphi) + U^{\text{or}}(\Omega, \varphi) \quad (18)$$

where $U^{\text{tors}}(\varphi)$ represents the torsional potential, and $U^{\text{or}}(\Omega, \varphi)$ the orientational contribution, which is now expected to depend upon the conformation assumed by the molecule.¹⁹

A multidimensional diffusion equation for both the orientational and the torsional degrees of freedom must be solved

in general but, under the hypothesis that internal and overall motions are decoupled, the two dynamic problems can be treated separately. Molecular reorientations are described by the diffusion model appropriate for uniaxial phases. In an analogous way, the conformational dynamics can be analyzed by solving a diffusion equation for the torsional variables. However, this procedure becomes impracticable when the number of internal degrees of freedom is greater than 3 or 4. An alternative method is based on the consideration that bond rotations are generally strongly hindered by intramolecular interactions, so that the internal potential has deep wells corresponding to a limited number of conformations. This is equivalent to assuming the so-called 'rotational isomeric state (RIS) approximation'.²⁰ It is therefore possible to resort to a kinetic description in terms of a master equation, for the random walk between stable conformers. This master equation can be set up phenomenologically, or be rigorously derived by asymptotic expansion of the diffusion equation in the potential minima.^{21,12} The following equation is obtained for the time evolution of $P_J(t)$, the J th conformer population:

$$\partial P_J(t)/\partial t = - \sum_{J'} W_{JJ'} P_{J'}(t) \quad (19)$$

where $W_{JJ'}$ is the rate constant for the $J' \rightarrow J$ transition. It is calculated by generalizing to the multidimensional case the Kramers result for barrier crossing in an overdamped regime.²² For the simple case of a single degree of freedom, as in the biphenyl molecule in which rotation about the phenyl-phenyl bond is hindered,²³ the rate constant k for a conformational jump is given by

$$k = (k_B T / 2\pi\xi) \omega_m \omega_M \exp \left\{ - \frac{\Delta E}{k_B T} \right\} \quad (20)$$

where ΔE is the barrier height, ξ is the friction exerted by the viscous medium, and ω_m and ω_M are the square roots of the potential curvature along the torsional coordinate, corresponding to the starting minimum and the top of the barrier, respectively.

The structure of the master equation and the expression of the transition rate remain essentially the same in isotropic or anisotropic liquids, but the presence of the orienting potential has a twofold effect:²⁴

1. A purely static effect, consisting in changes in the statistical weights of the various conformations. In calamitic nematics, the most elongated conformers can be more easily accommodated, and they are therefore stabilized at the expense of the most folded ones.
2. A dynamic effect, due to changes in the potential profile along the path of the conformational transitions, which modify the rates of such processes by altering the curvatures and activation energies.

Let us now consider mesogenic molecules formed by an elongated core and an aliphatic chain, such as those belonging to the alkylcyanobiphenyl series.²⁵ Conformational motions cause fast reorientations of the chain segments about the all-*trans* axis, and the whole molecule undergoes anisotropic rotational diffusion. Because of the inequivalence of the conformational sites, isomerization processes alone do not allow the chain segments to be isotropically distributed in space, and so a residual order with respect to the molecular

frame is left, even in isotropic phases. The liquid crystal environment enhances the segmental order by aligning the molecular axes. If there is a timescale separation between the conformational and the overall motions, two distinct processes contributing to spin relaxation can be easily identified. Fast internal motions partially average the interaction tensors located on the various molecular segments, at rates determined by the isomerization frequencies. The partially averaged magnetic tensors are then modulated by the slow anisotropic diffusion. The same conclusions apply to the case of chains anchored to surfaces and undergoing internal and wobbling motions, and thus this can be used as a model system for studies on micelles and membranes.¹³

For illustrative purposes, we report some results obtained for a model 12-bond chain with a fixed end. Each segment of the chain can exist in one of the three states called *gauche*₊ (g_+), *trans*, and *gauche*₋ (g_-). According to the RIS approximation,²⁰ 531 441 different conformers are possible for this system, but only about 257 000 are physically significant, the others being rejected for steric reasons. In an isotropic liquid, the statistical weight of any conformer is never larger than 0.001. Calculations for a liquid crystalline phase of intermediate ordering show that less than 40 conformers have a global statistical weight greater than 10%. These conformers obviously include the all-*trans* configuration, the others having a single *gauche* state at chain positions not far from the free end (a *gauche* state close to the headgroup would dramatically perturb the ordered environment), and the so-called kinks, i.e. conformers with $g_{\pm} t g_{\pm}$ sequences. In all these cases an approximately cylindrical molecular shape is retained. Figure 1 shows the order parameter for the C-H (or C-D) bond and the *gauche* $\rightarrow$ *trans* isomerization rate at each chain segment of the 12-bond chain, in the isotropic and the ordered phases. The anisotropic environment significantly increases the transition rates, and dramatically changes the order parameters. Modulation of the local ordering by slow wobbling motion of the chain axis may become the most relevant mechanism for spin relaxation in the liquid crystalline phase.

3.4 Translational Diffusion and Director Fluctuations

In principle, other kinds of motion, in addition to those described so far, may operate as relaxation mechanisms in

Figure 1 Order parameters and *gauche* $\rightarrow$ *trans* isomerization rates at the various segments of a substrate-supported 12-bond chain, in the isotropic (open symbols) and nematic (filled symbols) phase

liquid crystals. Since rotational diffusion and internal motion are dominant mechanisms for ^{13}C and ^2H spin probes at the high working frequency of standard spectrometers, they will be mentioned only briefly here.

One motional process common to all liquids is translational diffusion. This motion modulates intermolecular dipole–dipole interactions, and efficient spin relaxation results for proton nuclei, because of the abundance of hydrogen atoms in organic molecules. In the case of deuterated compounds, dipole interactions are reduced and intramolecular interactions remain, in practice, the only source of relaxation.

Another interesting process, which is specific to liquid crystal phases, results from elastic deformations of the ordered structures generated by collective thermal motions, which give rise to spontaneous alignment fluctuations. This process is responsible for the scattering of visible light, which in turn causes the turbid appearance of nematics. It also affects the spin relaxation, since it modulates the director orientation in the magnetic field. The corresponding spectral densities display characteristic frequency dependences. Director fluctuations may become the dominant relaxation mechanism at low-frequency regimes, but are relatively unimportant in high-field experiments.

1 INTRODUCTION

Proton (or other spin- $\frac{1}{2}$ nuclei) NMR spectra of molecules dissolved in liquid crystalline solvents differ from their isotropic analogues in a significant way. Thus, the well-known proton isotropic spectrum of ethylbenzene (composed of a triplet, a quadruplet and a broad singlet) changes into the ugly looking spectrum shown in Figure 1. Only by displaying the spectrum with a much smaller Hz/cm ratio is it possible to recognize the few thousand closely spaced, well-resolved, single transitions dispersed over a range of a few kilohertz which compose the spectrum. For molecules with a higher number of interacting spins the situation is even worse; the total intensity is dispersed over so many closely spaced, single transitions that their anisotropic spectra, except for a few highly symmetric spin systems, appear as a single unresolved band a few kilohertz in width. For this reason it is not necessary to use deuterated compounds as anisotropic solvents because the liquid crystalline phases used contain more than 20 interacting protons and contribute to the total spectrum only as the lumps and bumps which form the baseline. The lines due to the solute, which are much more intense because their total intensity is dispersed over relatively fewer transitions, can be distinguished from the baseline.¹

These differences arise because two extra terms have to be considered in the anisotropic Hamiltonian.¹ Within the usual high field approximation the Hamiltonian is given by

$$\begin{aligned}
 \hat{\mathcal{H}} = & \frac{1}{2\pi} \sum_i \gamma_i \hat{I}_{iz} (1 - \sigma_i^{\text{iso}} - \bar{\sigma}_{zzi}) B_z \\
 & + \sum_{i < j} \{ J_{ij}^{\text{iso}} [\hat{I}_{iz} \hat{I}_{jz} + \frac{1}{2} (\hat{I}_i^+ \hat{I}_j^- + \hat{I}_i^- \hat{I}_j^+)] \} \\
 & + \sum_{i < j} [\bar{J}_{zzij} + 2\bar{D}_{zzij}] [\hat{I}_{iz} \hat{I}_{jz} - \frac{1}{2} (\hat{I}_i^+ \hat{I}_j^- + \hat{I}_i^- \hat{I}_j^+)] \\
 & + \sum_i \frac{\bar{q}_{zzi}}{4I_i(2I_i - 1)} [3\hat{I}_{iz} \hat{I}_{iz} - I_i(I_i + 1)] \quad (1)
 \end{aligned}$$

where γ_i is the magnetogyric ratio of the i th nucleus. The fourth term is included only if $I_i \geq 1$, while the σ_i^{iso} and J_{ij}^{iso}

Figure 1 300 MHz (7.06 T) proton spectrum of ethylbenzene dissolved in ZLI 1132, a nematic solvent obtained from Merck

scalars, the trace of the σ shielding and J indirect spin-spin coupling tensors, are the well-known spectral parameters which determine isotropic spectra; $\bar{\sigma}_{zzi}$, $\bar{J}_{zzij}$, $\bar{D}_{zzij}$ and $\bar{q}_{zzi}$ are the averaged components of the shielding, indirect coupling, direct dipolar coupling, and quadrupolar coupling tensors, respectively. The last two tensors have a null trace and so do not influence the frequencies or intensities of the peaks in isotropic spectra.

The direct dipolar couplings are related to the molecular geometries by

$$\bar{D}_{zzij} = K_{ij} \sum_{\alpha\beta} G_{ij\alpha\beta} S_{\alpha\beta}, \quad \alpha, \beta = x, y, z \quad (2)$$

for rigid molecules, or

$$\bar{D}_{zzij} = K_{ij} \sum_n p^n \sum_{\alpha\beta} G_{ij\alpha\beta}^n S_{\alpha\beta}^m \quad (3)$$

if internal rotational motions are present. K_{ij} depends on the magnetogyric ratio of the i th and j th nuclei, p^n is the population of conformer n , $S_{\alpha\beta}^m$ are the elements of $\mathbf{S}^n$, the Saupe orientational matrix for conformer n , $G_{ij\alpha\beta}^n$ are related to the internuclear distance r_{ij} and to its orientation with respect to a Cartesian system x, y, z fixed on the molecule.

It should be noted that the observed differences are not just due to the extra parameters present, but also, and more importantly, to the wider range of values that they can assume (from 2.5 to -5 kHz for direct couplings, and up to several kilohertz for quadrupolar couplings). If spin systems composed of only spin- $\frac{1}{2}$ nuclei are considered (for a description of how quadrupolar couplings influence anisotropic spectra, see *Liquid Crystalline Samples: Deuterium NMR*), the fourth term in equation (1) is zero and the spectrum shape depends mainly on the values of the dipolar couplings. Two important consequences ensue from this fact: (a) all the nuclei in the molecule have dipolar couplings larger than the experimental linewidth (4–5 Hz); and (b) no first-order features are present in the spectra of homonuclear spin systems.

Two points follow from equation (1). First, the direct spin-spin coupling $\bar{D}_{zzij}$ cannot be measured separately from $\bar{J}_{zzij}$ because only the quantity

$$\bar{T}_{zzij} = \bar{D}_{zzij} + \frac{1}{2} \bar{J}_{zzij} \quad (4)$$

can be determined experimentally,^{1c} and so liquid crystal NMR can be used to determine the geometry only if the pseudodipolar couplings $\bar{J}_{zzij}$ are known independently. Experimental and theoretical studies have shown that the pseudodipolar term is usually much smaller than the dipolar coupling and so, with the exception of F–F couplings, $\bar{D}_{zzij}$ can be safely equated to $\bar{T}_{zzij}$ (see *Anisotropy of Shielding and Coupling in Liquid Crystalline Solutions*).

The second point involves magnetically equivalent nuclei (see *Magnetic Equivalence*). The frequencies and intensities in isotropic spectra do not depend on the values of the indirect couplings between nuclei belonging to the same magnetically equivalent group, but this is not the case for anisotropic spectra. In many spectra this just means that there is one more direct coupling for each magnetically equivalent group to be taken into account in anisotropic spectral analysis, but the effects are quite dramatic for A_n (where n is the number of interacting spins) spin systems. Benzene is a very good example; all six protons have the same chemical shift and so, even though there are three different indirect couplings (J_{ortho} , J_{meta} , and J_{para}), the isotropic spectrum shows only a single transition. The spin system is correctly defined as A_6 . The spectrum of benzene dissolved in an orienting medium will instead contain a maximum of 72 lines and is analyzable in terms of a chemical shift and three indirect and three direct couplings. The correct notation for the spin system is $AA'A''A'''A''''A'''''$.^{1b}

2 COMPUTER PROGRAMS FOR SPECTRAL ANALYSIS

For anisotropic spectra, analytical solutions are possible only for a very limited number of simple spin systems,^{1a,1b} but simulation/iteration programs are available for spectral analysis. These programs will: (a) calculate the spectrum from a trial starting set of spectral parameters using the spin Hamiltonian in equation (1); and (b) refine the parameters to fit some spectral quantities.²

A few methods have been proposed which use different spectral quantities in the fit, but only three of them have found application in anisotropic spectral analysis.

1. *Fully automated analysis*³ According to this approach the full spectrum (defined by a vector containing intensity values at a fixed frequency interval) is used in the iteration procedure. No operator intervention is needed during the iteration cycles; at the end of the procedure the operator checks if the experimental spectrum has been reproduced correctly and no false minimum found (for a more detailed description of the method and computer programs, see *Analysis of Spectra: Automatic Methods*).
2. *Swalen–Reilly method*⁴ The ‘experimentally’ determined energy level diagram (ELD) is used in the refinement program NMRIT.^{2,4b} The final parameter set, refined assuming a given assignment of calculated to experimental levels, is used to calculate the spectrum which is then compared with the experimental one. The procedure is repeated for a different assignment and the parameters giving the best fit between the calculated and experimental spectrum are assumed to be correct. The procedure can be easily automated, its main advantage deriving from

the relatively low number of distinct assignments.⁵ The algorithm which computes the ELD [part (a) of the program] must take into account the correct symmetry of the spin system.

3. *Castellano–Bothner-By method*⁶ By far the most widely used approach,² this method makes use of the experimental frequencies in the parameters’ refinement procedure. The method is particularly attractive because the derivatives

$$\frac{\partial F_{mn}}{\partial p_j} = \frac{\partial \Lambda_m}{\partial p_j} - \frac{\partial \Lambda_n}{\partial p_j} \quad (5)$$

where p_j is the j th spectral parameter, Λ_m is the m th eigenvalue, and F_{mn} is the calculated frequency of the transition between the m th and n th levels, can be calculated analytically. In fact,

$$\frac{\partial \Lambda_m}{\partial p_j} = \left(\mathbf{U} \frac{\partial \mathbf{H}}{\partial p_j} \mathbf{U} \right)_{mm} \quad (6)$$

where $\mathbf{U}$ is the matrix which diagonalizes the Hamiltonian matrix representation $\mathbf{H}$ in a given basis set. Care must be taken when choosing the basis set, in order to make as simple as possible the algorithm which computes the matrix $(\partial \mathbf{H} / \partial p_j)$.

Line identification numbers from a spectrum calculated with a trial, starting set of spectral parameters are assigned by the operator to experimental frequencies; the program will modify a selected subset of parameters to minimize the root mean square (rms) of the differences between the assigned calculated and experimental frequencies and will output the spectrum calculated with the new parameter set. The operator will compare the two spectra, recognize more lines to assign, modify or delete old assignments and choose a new subset of parameters to iterate. The cycles will be repeated until nearly all the experimental lines are assigned and a low rms obtained, having iterated the whole set of spectral parameters. The procedure is cumbersome, requiring a great deal of time and effort by the operator in the assignment step, and cannot be easily automated because only the operator can discriminate between the $N!$ different assignments (N being the number of observed transitions) on the basis of their intensities and relative positions. The probability of achieving success in the spectral analysis is low, decreases quickly as the complexity of the spin system increases, and is strictly related to the quality of the starting set, i.e. how near the starting parameter values are to the final ones.

To reduce the computational requirements [central processing unit (CPU) time and storage requirements] of part (a) of the program, much effort has been devoted to making full use of the possibilities of simplifying the Hamiltonian by using suitable basis function sets, but keeping operational the Castellano–Bothner-By iterative method. The first programs (LAOCOON^{6b} and its anisotropic counterpart LAOCONOOR) took into account the so-called Fz and X approximation factorization; magnetic equivalence factorization based on the Ferguson–Marquardt formalism⁷ (composite particle formalism) was introduced in the LEQUOR program⁸ in the early 1970s.

Molecular symmetry can also be used to factorize the Hamiltonian matrix if the basis function sets which are used belong to the irreducible representation of the permutation

group of the spin system.² This leads to an increase in the complexity of the algorithm which computes: (i) the elements of the Hamiltonian and transition probability matrices, and (ii) the analytical derivatives ($\partial \mathbf{H} / \partial p_i$) in the basis set used. However, computational efficiency is greatly increased. Simulation programs which make full use of molecular symmetry exist,⁹ but the iterative part has been implemented only for the C_2 permutation group (program LACX^{2,10}).

The two formalisms (composite particle and symmetry factorization) have been combined in the ARCANA program,¹¹ which has been used to analyze such complex spin systems as those arising from the 11 protons in 4-methoxy-4'-cyanobiphenyl¹² (an AA'BB'CC'DD'E₃ spin system).

CPU times can be further reduced if more efficient ordering routines are used. The gain is quite impressive for complex spin systems, resulting in the astonishingly short time of 2 min when a Shell-Metzner ordering¹³ routine was used. This compares with 102 min for the commonly used Bubble-Sort¹³ for the AA'BB'CC'XX'Y₃ ($I_A = I_B = I_C = \frac{1}{2}$, $I_X = I_Y = 1$) spin system which gives more than 10 000 transitions, and was simulated on a VAX 11/780¹⁴ using the ARCANA program. More efficient diagonalization routines give better total performance in the simulation step, but some problems arise when they are used in the iterative step. In fact, depending on the diagonalization algorithm used, pairs of eigenvalues can change their positions arbitrarily; the line numbers change in an unpredictable way and the iteration fails. Rough prediagonalization, according to Castellano et al.,^{6a} can eliminate this inconvenience if Jacobi based diagonalization routines are used.

Computer hardware is now improving at such a fast rate that the latest generation of workstations have performances in terms of mips (million instructions per second), main memory and mass storage, which are similar to, if not greater, than the largest mainframes of 10 years ago. In fact, the most important differences between programs is not now in their efficiency in simulating the spectra, or even in the iteration procedure, but rather in their ability to produce a visual representation of the spectrum on the terminal, and in the ease of assigning transitions to observed frequencies.

3 OBTAINING STARTING PARAMETERS FOR ITERATIONS

Remembering the wide range of allowed values of D_{ij} , it is easy to understand the enormous difficulties faced in analyzing anisotropic spectra. When the line density in the spectrum is low (few nuclei, strongly oriented spin systems), very approximate estimates of the D_{ij} values can quite easily give frequency/intensity patterns in the calculated spectra that can be recognized in the experimental spectra. When the spectra become crowded (the one shown in Figure 1 is a good example), a completely random trial-and-error approach is hopeless; more systematic and efficient methods have to be devised to ensure at least some probability of success in the analysis. Sometimes the spectral parameters can be guessed either from a comparison with data for similar molecules (or the same molecule in a different solvent) or from the shape of the spectrum.

The spectra of the pyridine-I₂ complex¹⁵ shown in Figure 2 illustrate this point very well. At high concentrations

Figure 2 100 MHz (2.34 T) proton spectra of [¹⁴N]pyridine in phase IV (Merck); the quantity of added I₂ increases from the top (0 mol% with respect to pyridine) to the bottom (60 mol%). The axis of highest order is perpendicular to the ring for free pyridine, parallel to the N-I-I direction for the complex. (Reproduced by permission of Royal Chemical Society from D. Catalano, C. A. Veracini, P. L. Barili, and M. Longeri, *J. Chem. Soc., Perkin Trans. II*, 1983, 171)

of the complex, the spectrum looks fairly simple, displaying even some first-order features such as the pentuplet-like multiplet in the center of the spectrum. The two outer groups can then be thought to be due to the *ortho* and *meta* protons, the distance between the groups being related to the D_{om} coupling, while the spacing between two consecutive lines in the central multiplet is equal to $D_{op} + D_{mp}$. In addition, the chemical shifts can be guessed approximately. This behavior is due to the fact that the molecule is strongly oriented with its molecular long axis tending to lie parallel to the mesophase director. When this happens, D_{om} has a large negative value (below -1000 Hz), while both D_{op} and D_{mp} are, in absolute value, much smaller. (Note that the *ortho*-*meta* and *meta*-*para* distances are nearly the same but the direction of the interproton vector with respect to the director is very different.) For pyridine, where the N-*para*-proton axis is, on average, perpendicular to the mesophase

director, the spectrum is featureless, and no estimates of spectral parameters can be made.

A more general strategy is to prepare a solution of the fully protonated and perdeuterated isotopomers. The $S_{\alpha\beta}$ obtained from the analysis of the ^2H spectra (see *Liquid Crystalline Samples: Deuterium NMR*) can be used to calculate approximate dipolar couplings from trial structures. The method works fairly well for rigid molecules, but it is not so efficient when internal rotation motions are present in the molecule (see *Liquid Crystalline Samples: Structure of Nonrigid Molecules*). Examples of this approach are the analysis of the ^1H spectra of biphenyl¹⁶ and 4-cyanobiphenyl.¹⁷

Alternatively, keeping an approximate molecular structure constant, it is possible to iterate over the $S_{\alpha\beta}$ values. Because the number of the variables is small (usually two or three), the approximate solution is quickly found.¹⁸ The final parameter set is then obtained by iterating over the dipolar couplings independently.

As soon as the number of interacting spins increases, such simple considerations can no longer be applied. Monosubstituted benzenes display a behavior similar to the one already described. When the substituent does not contain protons, its spectrum looks like the one at the bottom of Figure 2, but if some interacting nucleus is present the complexity of the spectrum increases in two ways: (i) the number of the transitions increases because of the extra couplings; and (ii) groups of transitions due to these nuclei can overlap with some of the features due to the aromatic protons. This is precisely what happens for the spectrum of anisole, where the OCH_3 transitions fall in the same spectral region as the *para* proton.¹⁹

If these extra nuclei have different magnetogyric ratios only point (i) has to be taken into account, and first-order features due to the couplings between nuclei with different magnetogyric ratios appear in the spectrum. Such is the case for trideuteromethoxybenzene²⁰ (anisole- d_3) for example, where each transition of the aromatic protons is split into a septet: the septets in the outer wings are spaced by a distance approximately equal to the sum of the *ortho*- CD_3 and *meta*- CD_3 couplings, whilst the central septets are spaced by the *para*- CD_3 coupling. Being able to recognize all these structures in the spectrum, makes it possible to obtain very good values for the extra couplings and, in addition, to obtain the 'decoupled' spectrum due to the aromatic protons by selecting the central lines of each multiplet. What is left to be analyzed is just a five-spin $\text{AA}'\text{BB}'\text{C}$ system, the spectrum of which would look like the one shown at the bottom of Figure 2. Such a spectrum can be analyzed easily. This is the case for anisole dissolved in ZLI 1115; the spectrum in I35 showed very few septet structures, and so it was not possible to determine the 'decoupled' $\text{AA}'\text{BB}'\text{C}$ spin system.²⁰

A similar approach proved to be possible for the four-proton, six-deuterium $\text{AA}'\text{A}''\text{A}'''\text{X}_3\text{X}'_3$ spin system of 1,4-bis(trideuteromethoxy)benzene.¹¹ The proton spectrum is composed of two complex, well-spaced groups of lines, the spacing of which is related to the coupling between the two *ortho* aromatic protons. The $\text{AA}'\text{A}''\text{A}'''$ spin subsystem would give the very simple spectrum shown in Figure 3, according to that obtained for symmetrically *para*-disubstituted halobenzenes. Each line would then be split into 13 subspectra corresponding to the values of m_T , the total deuteron spin quantum number, by coupling with the six deuterons: for $m_T = \pm 6, \pm 5, \pm 4,$

Figure 3 Sketch of the spectrum of an $\text{AA}'\text{A}''\text{A}'''$ system of spin-1/2 nuclei with dipolar coupling constants typical for a *para*-homodisubstituted benzene, showing how transitions are connected. (Reproduced by permission of Royal Chemical Society from J. W. Emsley, D. L. Turner, A. Giroud, and M. Longeri, *J. Chem. Soc., Faraday Trans. 2*, 1985, **81**, 603)

$\pm 3, \pm 2, \pm 1$, and 0, the intensities would be 1, 6, 21, 50, 90, 126, and 141, respectively. Trying to recognize all the 13 subspectra by eye is hopeless; in this case the task was easily accomplished by doing a two-dimensional homonuclear correlation experiment.

For an $\text{AA}'\text{A}''\text{A}'''$ spin system spectrum, such as the one shown in Figure 3, only two lines (the most intense ones) within the two groups share the same energy level, all the other connections being between symmetric lines belonging to the different groups. As a consequence, the off-diagonal peaks near the diagonal reveal the position of the two connected lines in each subspectrum. As shown in Figure 4, only 8 of the 13 off-diagonal peaks expected on each side of the main diagonal are visible. The lines belonging to the $m_T = 0$ subspectrum were easily spotted and then, with little effort, nearly all the subspectra (the less intense lines of the $m_T = \pm 6$ subspectra are lost in the noise) were recognized.

Such elegant ways of analyzing anisotropic spectra are quite uncommon. Very often spectral analysis is an unglamorous, boring, and long task, with many unrewarding days spent in front of a terminal with little or no hope of disentangling patterns that can be recognized from the maze of lines in the experimental spectrum and few exciting moments occur when the lines begin to assume the right frequency and intensity pattern and the main features appear in the calculated spectrum.

4 STRATEGIES IN SPECTRAL ANALYSIS

Two main strategies have been developed to try to simplify the analysis of spectra: one is aimed mainly at reducing human

Figure 4 200 MHz (4.69 T) proton autocorrelation spectrum of 4-bis(trideuteromethoxy)benzene dissolved in the liquid crystal PCH 1132 (Merck). (Reproduced by permission of Royal Chemical Society from J. W. Emsley, D. L. Turner, A. Giroud, and M. Longeri, *J. Chem. Soc., Faraday Trans. 2*, 1985, **81**, 603)

intervention by using automated methods, and the other is aimed at simplifying spectral analysis by obtaining simpler experimental spectra.

4.1 Fully Automated Approaches

Two different approaches use the first strategy. The first approach (mentioned previously) has been used to analyze the anisotropic spectra of three allyl halides²¹ and of cyclopentene,²² an eight-spin system. The second approach makes use of the Swalen–Reilly iterative method. The use of the latter method is limited, mainly because an ‘experimental’ ELD is needed. Programs and/or experimental methods devoted to this task have been proposed,² but the complexity and peculiar characteristics of anisotropic spectra make them unsuitable candidates for analysis in this way. Pfändler and Bodenhausen⁵ have proposed a two-dimensional z correlation spectroscopy (z COSY) experiment for constructing experimentally the ELD for a given spin system. Using different values of the β flip angle of the pulse sequence

$$\frac{\pi}{2} - t_1 - \beta - \tau_m - \beta - t_2 \quad (7)$$

the authors showed that it is possible to determine the topology of two connected frequencies by observing how

the intensity of the cross peak varies with β . Knowing the topology of the connections for nearly all the observed lines in the spectrum, the energy level subdiagram for an A_3B and an A_2BC spin system were constructed, even when some connections were determined incorrectly. For each different possible assignment (864 for the A_2BC , and 8 for the A_3B spin system), the spectral parameter set was refined according the Swalen–Reilly iterative method. The spectrum was calculated and the best assignment was chosen by comparing the calculated and experimental spectra.

A generalization of the method would require a library containing topologies of ELDs for spin systems of different symmetries. Improvements are needed to take into account the extensive degeneracy that can occur for larger spin systems. Such degeneracies can be due either to accidental overlaps of lines in crowded spectral regions or to the poor digital resolution of the two-dimensional spectra of liquid crystalline phases.

4.2 Spectral Simplification Based Approaches

As an alternative approach to the automated methods, experiments aimed at reducing the complexity of spectra can be planned. In this way spectral analysis will be simplified and the rate of success increased.

4.2.1 Spectral Simplification via Deuterium Decoupling

Selectively deuterated molecules give quite complex ^1H spectra (the anisole- d_3 spectrum in ZLI 1115 being a lucky exception), even if, at first glance, they look fairly simple. There are, in fact, a larger number of lines in such spectra, as deuterium has $I = 1$ while the larger linewidth, due to the ^2H quadrupolar relaxation, combined with the lower values of the D_{HD} couplings ($\gamma_{\text{H}}/\gamma_{\text{D}} \simeq 6$), causes widespread overlapping of transitions.

Spectral simplification can be obtained by performing $\{^2\text{H}\}-^1\text{H}$ decoupling experiments, and good results have been obtained with solenoid probes. Using short acquisition times ($<0.2\text{ s}$) when the decoupler is on, and a delay of typically 3 s to allow cooling to occur and to reduce thermal inhomogeneities, decoupled spectra from complex spin systems such the eight protons in 4-trideuteromethoxy-4'-cyanobiphenyl¹² have been recorded and successfully analyzed.

The procedure just described is the one usually followed when complex spectra are analyzed using this approach: ^1H spectra (with and without deuterium decoupling) of different selectively perdeuterated isotopomers are recorded under similar experimental conditions (solvent, temperature and concentration) and analyzed from the simpler to the more complex spin systems in order to obtain a good starting parameter set for the analysis of the spectrum of the fully protonated molecule. The full procedure requires much synthetic and spectral analysis work, but it is applicable whenever selective deuteration is possible and gives a very high success rate—its upper limits being an analyzable ^1H spectrum of the fully protonated species.

As an alternative to the high power decoupling technique, the sequence which refocuses heteronuclear coupling,

$$\left(\frac{\pi}{2}\right) - \tau_1 - (\pi) - \tau_1 - \text{Sample} \quad (8)$$

can be used:²³ τ_1 is increased at fixed intervals and the first point of each FID taken at the top of the echo is stored in a vector. The vector is Fourier transformed to give the decoupled, $\Delta\nu_i = 0$ spectrum. In fact the selective pulse sequence is such that at the top of the echo the magnetization does not depend on the heteronuclear couplings. The experiment takes a long time and has lower sensitivity than decoupling. In addition, artifacts due to pulse and phase imperfections have to be considered, but these can be significantly reduced in modern instrumentation. The spin echo experiment has the great advantage that all the heteronuclear couplings due to nuclei with different γ values are decoupled at once. If the antiecho is recorded, homonuclear couplings are refocused and the spectrum depends only on heteronuclear couplings (see *Spin Echo Spectroscopy of Liquid Samples*).

4.2.2 Spectral Simplification via Multiple Quantum Spectroscopy

This approach is discussed elsewhere (see *Multiple Quantum Spectroscopy in Liquid Crystalline Solvents*). Here it is sufficient to remember that for a given spin system composed

of N nonequivalent spins $\frac{1}{2}$, the maximum possible number of transitions of order p is

$$Z_p = \binom{2N}{N-p} \quad (9)$$

for $1 \leq p \leq N$.²⁴ It is clear that even a very complex spin system will give simple spectra when p is $N - 1$ or $N - 2$ and these spectra will contain the same information that can be obtained from the single quantum ordinary spectrum with

$$Z_p = \binom{2N}{N-1} \quad (10)$$

4.2.3 Double Quantum Two-Dimensional Correlated Experiments

In a series of very elegant papers, Pines et al. applied multiple quantum (MQ) spectroscopy to a class of compounds, the n -alkanes, whose proton spectra are too complex to analyze. The molecules chosen, from n -hexane²⁵ to n -decane,²⁶ were randomly perdeuterated in such a way to have a negligible population of isotopomers with more than three protons left, but with all the possible two- and three-protonated isotopomers having a nearly uniform population distribution. This is easily done via a catalytic exchange reaction for n -alkanes, but the required population distribution may not be reached in such a direct way for other molecules having functional groups. This limits the generalization of the method to other organic compounds. A two quantum filtered experiment reduces the complexity of the spectrum leaving only AB and A_2 (16 for n -hexane) spin systems. A four-step phase cycling keeps the total number of averaged FIDs for each t_1 (96 for 24 increments in τ ²⁵) acceptably low, to ensure a digital resolution of nearly 30 Hz per point. The phase cycling selects even quantum coherences: the sweep width is then kept small by the isotopomer population distribution because no four or higher coherences are possible. On the other hand, it is crucial that the double quantum coherence of all the AB spin systems is present. As the D_{ij} values cover a wide range, this can be achieved only by coadding FIDs obtained with different τ values; the data acquisition time will thus be lengthened significantly. To distinguish signals belonging to different spin systems, a two-dimensional correlation experiment can be performed. The two last steps are possible using the pulse sequence

$$\begin{aligned} &\left(\frac{\pi}{2}\right)_\phi - \tau - \left(\frac{\pi}{2}\right)_\phi - \frac{t_1}{2} - (\pi) - \frac{t_1}{2} - \left(\frac{\pi}{2}\right)_x \\ &- \frac{\tau_2}{2} - (\pi) - \frac{\tau_2}{2} - t_2 \end{aligned} \quad (11)$$

All the spectra were recorded with continuous deuterium decoupling,²⁷ which causes considerable heating and thermal inhomogeneities, despite air-flow temperature control. All the couplings (up to 20 for n -decane) were determined with an experimental error of about 25 Hz, the low accuracy being a consequence of the low digital resolution and thermal gradients.

4.2.4 Spectral Simplification via Scaling of Dipolar Couplings

As previously stated, one of the reasons for the complexity of anisotropic spectra is the non-first-order character of the

spectra. Another way to simplify the analysis of such spectra is to scale the direct couplings by some factor, thus leaving only a few couplings (the biggest) that are greater than the spectral linewidth. In this way first-order features will appear in the spectrum if the chemical shift differences are large enough, and the number of lines in the spectrum will be reduced. In principle, all these improvements could be achieved simply by changing the experimental conditions that decrease the solute order (temperature and/or solute concentration), but this is in practice unachievable because the **S** matrix changes discontinuously at the nematic–isotropic transition temperature T_{NI} .

Courtieu et al.²⁸ applied the variable angle technique (using a spinning angle of 51°), developed for NMR in solids, to scale dipolar couplings, thus reducing the ABC pattern in CF₂CFBr to a first-order, easily analyzable AMX spectrum. At lower angles, non-first-order features began to appear but, because the authors were able to register the spectra at lower spinning angles, the line patterns can be easily followed and the dipolar couplings calculated at a spinning angle of 0° (*Spinning Liquid Crystalline Samples*).

Scaling of dipolar couplings can be achieved by using a suitable pulse sequence (PARDES) derived from the well-known WAHUA and MREV sequences,²⁹ as described by Frydman et al.³⁰ The reduction in the splitting of the doublet due to CH₂Cl₂ dissolved in a nematic mesophase was followed by varying the parameters in the sequence.

1 INTRODUCTION

Both whole molecule and internal modes of motion are rapid enough that the dipolar couplings D_{ij} and the quadrupolar splittings $\Delta\nu_i$ which are obtained by analysis of the NMR spectrum of a sample in a liquid crystalline phase are averages over these motions. This means that, in principle, it is possible to investigate the internal motion via these averaged values, and indeed this is proving to be a valuable method for studying the flexibility of molecules in a liquid phase.

It also means that investigations of the orientational order by NMR must take the internal motion into account. NMR studies have in fact played the central role in demonstrating that molecules which form liquid crystalline phases (mesogens) are flexible, and in stimulating the development of molecular statistical theories of orientational order which allow for the internal motion. Perhaps the most important step was the realization that orientational order and internal motion are inextricably linked together.¹⁻³ This has the consequence that it is not possible to describe the orientational order by a single Saupe order matrix S (see *Liquid Crystals: General Considerations*), but it is necessary to recognize that the elements of this matrix depend on the internal coordinates, that is they are conformationally dependent.

All mesogens discovered so far are flexible, and this should be taken into account when interpreting any measurements (not only NMR) made on them in terms of the behavior of the molecules. This is now recognized by many, although not all, in the NMR community. In the case of relaxation rates it is difficult to do this rigorously, but models of varying degrees of sophistication are used (see *Liquid Crystalline Samples: Relaxation Mechanisms* and *Liquid Crystalline Samples: Deuterium NMR*). This aspect is not discussed further here.

2 AVERAGING OF DIPOLAR AND QUADRUPOLEAR INTERACTIONS FOR NUCLEI IN FLEXIBLE MOLECULES IN LIQUID CRYSTALLINE SAMPLES

These are totally anisotropic interactions and so NMR experiments yield the components $T_d^{(2,m)}$ in a frame fixed on the mesophase director, and the spherical, irreducible tensor notation is used (see *Liquid Crystals: General Considerations*). These are related to $T_d^{(2,m)}(\alpha, \beta, \gamma, \{\phi\})$, the values for the molecule at a fixed orientation, described by the three Euler angles α , β , and γ for the conformation described by the set of internal angles $\{\phi\}$. Thus,

$$T_d^{(2,m)} = \int T_d^{(2,m)}(\alpha, \beta, \gamma, \{\phi\}) P_{LC}(\alpha, \beta, \gamma, \{\phi\}) \times \sin \beta d\beta d\alpha d\gamma d\{\phi\} \quad (1)$$

$T_d^{(2,m)}(\alpha, \beta, \gamma, \{\phi\})$ is known for a fixed geometry of the molecule, and so the unknown quantity in equation (1) is $P_{LC}(\alpha, \beta, \gamma, \{\phi\})$, which is the singlet, orientational distribution function for the molecules in the conformation specified by $\{\phi\}$. The object of NMR experiments on flexible molecules is to obtain this function. All properties of the ensemble of molecules which depend only on single molecules can then be calculated from $P_{LC}(\alpha, \beta, \gamma, \{\phi\})$.

The probability, $P_{LC}(\{\phi\})$, that a molecule is in the conformation $\{\phi\}$ independently of its orientation relative to the director is obtained as

$$P_{LC}(\{\phi\}) = \int P_{LC}(\alpha, \beta, \gamma, \{\phi\}) d\alpha \sin \beta d\beta d\gamma \quad (2)$$

This function describes the conformational distribution of the molecules in the liquid crystalline phase. In general, this will differ from $P_{iso}(\{\phi\})$, which describes the conformational distribution of the molecule, at the same temperature, in an isotropic phase of the sample.

Conformationally dependent order parameters are defined as

$$\langle D_{m,n}^{2*}(\{\phi\}) \rangle = \int D_{m,n}^{2*}(\alpha, \beta, \gamma, \{\phi\}) \times P_{LC}(\alpha, \beta, \gamma, \{\phi\}) d\alpha \sin \beta d\beta d\gamma \quad (3)$$

where $D_{m,n}^{2*}(\alpha, \beta, \gamma, \{\phi\})$ is the Wigner function describing the transformation from molecule to director fixed axes when the molecule is in conformation $\{\phi\}$.

2.1 Conformationally Dependent Saupe Order Parameters

The spherical tensor notation is particularly helpful when describing phases of different symmetries, but most NMR experiments are done either on uniaxial phases, or on biaxial phases with their director frame aligned with the applied magnetic field B_0 . In these cases the experiments yield just $T_d^{(2,0)}$, and it is more convenient to use Cartesian representations of the tensors. For example, an averaged dipolar coupling, D_{ij} , is now given by

$$D_{ij} = \int P_{LC}(\{\phi\}) D_{ij}(\{\phi\}) d\{\phi\} \quad (4)$$

where

$$D_{ij}(\{\phi\}) = -(\mu_0/4\pi)(h\gamma_i\gamma_j/4\pi^2r_{ij\{\phi\}}^3)S_{ij}(\{\phi\}) \quad (5)$$

and $S_{ij}(\{\phi\})$ is a conformationally dependent order parameter. Transforming $\mathbf{S}(\{\phi\})$ to give components $S_{\alpha\beta}(\{\phi\})$ in a frame fixed in a rigid subunit of the molecule gives

$$\begin{aligned} D_{ij}(\{\phi\}) = & -(\mu_0/4\pi)(h\gamma_i\gamma_j/8\pi^2r_{ij\{\phi\}}^3)[S_{zz}(\{\phi\})(3\cos^2\theta_{ijz\{\phi\}} - 1) \\ & + (S_{xx}(\{\phi\}) - S_{yy}(\{\phi\}))(\cos^2\theta_{ijx\{\phi\}} - \cos^2\theta_{ijy\{\phi\}}) \\ & + 4S_{xy}(\{\phi\})\cos\theta_{ijx\{\phi\}}\cos\theta_{ijy\{\phi\}} \\ & + 4S_{xz}(\{\phi\})\cos\theta_{ijx\{\phi\}}\cos\theta_{ijz\{\phi\}} \\ & + 4S_{yz}(\{\phi\})\cos\theta_{ijy\{\phi\}}\cos\theta_{ijz\{\phi\}}] \end{aligned} \quad (6)$$

where $\theta_{ij\alpha\{\phi\}}$ is the angle between $\mathbf{r}_{ij\{\phi\}}$ and the α axis in the conformation specified by $\{\phi\}$. Similarly, the doublet splitting $\Delta\nu_i$ observed for a deuteron in a flexible molecule is given by

$$\Delta\nu_i = \frac{3}{2}q_{aai}[S_{aa}(\{\phi\}) + \frac{1}{3}\eta_i(S_{bb}(\{\phi\}) - S_{cc}(\{\phi\}))] \quad (7)$$

where abc are principal axes for either the quadrupolar tensor $\mathbf{g}_i$, or for the conformationally dependent order matrix $\mathbf{S}(\{\phi\})$.

2.2 Averaging over Single Sets of Symmetry-Related Conformations

For some molecules a reasonable approximation of the conformational distribution is that only a set of minimum energy conformations is populated [which is often referred to as the ‘rotational isomeric state’ (RIS) model], and that these are related by symmetry. The molecules are assumed to jump between these conformations, and this will be referred to as the ‘jump model.’ For example, if benzaldehyde is interconverting between two, planar conformations which are related by a mirror plane (Scheme 1), then if all other conformations are neglected:

$$S_{xx}(\mathbf{1}) = S_{xx}(\mathbf{2}), \quad S_{yy}(\mathbf{1}) = S_{yy}(\mathbf{2}), \quad S_{zz}(\mathbf{1}) = S_{zz}(\mathbf{2}) \quad (8a)$$

$$S_{xy}(\mathbf{1}) = S_{xy}(\mathbf{2}) = 0 \quad (8b)$$

$$S_{xz}(\mathbf{1}) = -S_{xz}(\mathbf{2}) \quad (8c)$$

$$S_{yz}(\mathbf{1}) = S_{yz}(\mathbf{2}) = 0 \quad (8d)$$

The observed and calculated dipolar couplings can be brought into agreement by adjusting the values of these order parameters.

Scheme 1

Scheme 2

Equation (4) for a set of n discrete conformations becomes

$$D_{ij} = \sum_n P_{LC}(n) \sum_{\alpha\beta} S_{\alpha\beta}(n) D_{ij\alpha\beta}(n) \quad (9)$$

with

$$\begin{aligned} D_{ij\alpha\beta}(n) = & -(\mu_0/4\pi)(h\gamma_i\gamma_j/8\pi^2r_{ijn}^3) \\ & \times (3\cos\theta_{ijn\alpha}\cos\theta_{ijn\beta} - \delta_{\alpha\beta}) \end{aligned} \quad (10)$$

where $\delta_{\alpha\beta}$ is unity if $\alpha = \beta$, and zero otherwise.

2.3 Averaging over Conformations Unrelated by Symmetry

Now it is no longer possible to obtain a unique set of order matrices from the NMR (or any other!) data. The essence of the problem is illustrated by an *ortho*-substituted benzaldehyde interconverting between two planar conformations (Scheme 2). In this case,

$$\begin{aligned} D_{ij} = & \sum_{\alpha\beta} P_{LC}(\mathbf{3}) S_{\alpha\beta}(\mathbf{3}) D_{ij\alpha\beta}(\mathbf{3}) \\ & + P_{LC}(\mathbf{4}) S_{\alpha\beta}(\mathbf{4}) D_{ij\alpha\beta}(\mathbf{4}) \end{aligned} \quad (11)$$

and since $P_{LC}(\mathbf{3}) \neq P_{LC}(\mathbf{4})$, and $S_{\alpha\beta}(\mathbf{3}) \neq S_{\alpha\beta}(\mathbf{4})$ are unknown, then only the products [known as weighted order parameters $P_{LC}(n)S_{\alpha\beta}(n)$] can be obtained from the data. This has not been done for *ortho*-substituted benzaldehydes, although this would be possible since there are more dipolar couplings (ten) than unknown weighted order parameters (six). An analysis of this kind has been done for the more complex case of 1-ethoxy-4-chlorobenzene.⁴

For multiple conformational states, or more generally when rotation about a bond is described by a continuous function $P_{LC}(\phi)$, then the observed NMR data must be compared with values calculated from models for both $P_{LC}(\phi)$ and $S_{\alpha\beta}(\phi)$, in other words, a model for $P_{LC}(\beta, \gamma, \phi)$.

3 THE MAXIMUM ENTROPY METHOD

This is the least biased approach to obtaining $P_{LC}(\beta, \gamma, \{\phi\})$, and was suggested initially by Zannoni,³ and subsequently first demonstrated by application to the study of substituted biphenyls dissolved in liquid crystalline solvents by Catalano et al.⁵

Recalling that an NMR experiment on a sample in an aligned uniaxial phase (the discussion will be restricted to this

case, although the method can be extended to the more general biaxial solvent) yields values of $T_{dk}^{(2,0)}$, the spherical tensor components of a set of k dipolar or quadrupolar interactions, then application of the maximum entropy principle leads to

$$P_{LC}(\beta, \gamma, \{\phi\}) = Z^{-1} \exp \left\{ - \sum_k \lambda_k T_k^{(2,0)}(\beta, \gamma, \{\phi\}) \right\} \quad (12)$$

where

$$Z^{-1} = \int P_{LC}(\beta, \gamma, \{\phi\}) \sin \beta \, d\beta \, d\gamma \, d\{\phi\} \quad (13)$$

and $T_k^{(2,0)}(\beta, \gamma, \{\phi\})$ is the component in a frame fixed in a rigid part of the molecule; the λ_k are adjustable parameters. For deuterium quadrupolar splittings ν_k , k will range over the number of different experimental values, and for dipolar couplings D_{ij} , λ_k must be replaced by λ_{ij} . The λ_k or λ_{ij} values are varied in order to bring calculated and observed data into agreement.

The maximum entropy method is very attractive in that no assumptions are necessary about the functional form of the rotational potentials, and it does not go beyond the information content of the data. This latter point must be recognized when interpreting the $P_{LC}(\{\phi\})$ obtained by a maximum entropy analysis. Thus, the shape of $P_{LC}(\{\phi\})$ depends to some extent on the degree of orientational order of the molecules in the liquid crystalline sample. This is illustrated in Figure 1, which shows the results from applying the maximum entropy method to sets of dipolar couplings simulated for the molecule 4,4'-dichlorobiphenyl (DCB), in a fixed conformation with an interring angle of 34° , and dissolved in a liquid crystal phase such that the values of S_{zz} of DCB vary from 0.2 to 0.6, in each case with $S_{xx} - S_{yy} = 0.02$. The $P_{LC}(\phi)$ in each case should be a pair of delta functions at 34° and 146° , but the maximum entropy method gives continuous distributions peaked at these values but which become flatter as S_{zz} decreases. If $S_{zz} = S_{xx} - S_{yy} = 0$, then $P_{LC}(\beta, \gamma, \phi)$ and $P_{LC}(\phi)$ obtained from the data would both be completely flat and independent of β , γ , and ϕ . At the other extreme of complete order, $S_{zz} = 1$ and $S_{xx} - S_{yy} = 0$, the distribution $P_{LC}(\phi)$ derived from

Figure 1 The probability distribution $P_{LC}(\phi)$ obtained by the maximum entropy method from simulated dipolar couplings for 4,4'-dichlorobiphenyl dissolved in an uniaxial solvent. The three curves are for $S_{zz} = 0.6$ (. . .), 0.4 (---) and 0.2 (—), in each case with $S_{xx} - S_{yy} = 0.02$

the data would not be the pair of delta functions, since the maximum entropy method assumes a smooth dependence on ϕ , but a close approximation to the true distribution would be obtained.

Another important point about the maximum entropy method is that it cannot yield $P_{iso}(\phi)$, the probability distribution for an isotropic phase. To illuminate this point, and to set the scene for the other methods of analyzing NMR data on flexible molecules, it is useful to define a mean potential $U(\beta, \gamma, \{\phi\})$ as

$$P_{LC}(\beta, \gamma, \{\phi\}) = Z^{-1} \exp[-U(\beta, \gamma, \{\phi\})/kT] \quad (14)$$

with

$$Z = \int \exp[-U(\beta, \gamma, \{\phi\})/kT] \sin \beta \, d\beta \, d\gamma \, d\{\phi\} \quad (15)$$

The maximum entropy method derives a mean potential which is entirely anisotropic, and which vanishes in the isotropic phase, in other words a *potential of mean torque*.

4 ADDITIVE POTENTIAL METHODS

These methods differ fundamentally from the maximum entropy method in that they depend on modeling the mean potential, which means that they provide biased estimates of the distribution functions. This does have advantages, in particular that it is now possible to obtain both $P_{LC}(\{\phi\})$ and $P_{iso}(\{\phi\})$, and the dependence of the derived distribution functions on orientational order disappears.

The basic idea is to express $U(\beta, \gamma, \{\phi\})$ as a sum of two terms:

$$U(\beta, \gamma, \{\phi\}) = U_{ext}(\beta, \gamma, \{\phi\}) + U_{int}(\{\phi\}) \quad (16)$$

with $U_{ext}(\beta, \gamma, \{\phi\})$ being a potential of mean torque, and $U_{int}(\{\phi\})$ that part of the mean potential which depends only on $\{\phi\}$, and which does not vanish in the isotropic phase. Thus,

$$P_{iso}(\{\phi\}) = Q^{-1} \exp[-U_{int}(\{\phi\})/kT] \quad (17)$$

with

$$Q = \int \exp[-U_{int}(\{\phi\})/kT] d\{\phi\} \quad (18)$$

$P_{LC}(\{\phi\})$ is also obtained by the additive potential methods, from equation (2), and in general will differ from $P_{iso}(\{\phi\})$.

Several ways of modeling $U_{ext}(\beta, \gamma, \{\phi\})$ have been proposed, and some of these are discussed in the following sections. Models for $U_{int}(\{\phi\})$ may also vary, and are often specific to the molecule under consideration and the amount of experimental data available from which they may be characterized.

4.1 The Independent Fragment Model for $U_{\text{ext}}(\beta, \gamma, \{\phi\})$

This model was introduced first by Marcelja,⁶ and subsequently modified by Emsley et al.,⁷ it is the latter model which is discussed here. We shall refer to this as the ‘AP method’. The potential of mean torque is assumed to be second rank in its orientational dependence:

$$U_{\text{ext}}(\beta, \gamma, \{\phi\}) = -\epsilon_{2,0}(\{\phi\})C_{2,0}(\beta, \gamma) - 2 \text{Re} \epsilon_{2,2}(\{\phi\})C_{2,2}(\beta, \gamma) \quad (19)$$

The $C_{2,m}(\beta, \gamma)$ are modified spherical harmonics, and the conformationally dependent interaction parameters $\epsilon_{2,m}(\{\phi\})$ are assumed to be sums of contributions $\epsilon_{2,p}(j)$ from contributions from each of j rigid subunits of the molecule:

$$\epsilon_{2,m}(\{\phi\}) = \sum_p D_{p,m}^2(\Omega_j) \epsilon_{2,p}(j) \quad (20)$$

where Ω_j is the orientation of fragment j with respect to reference axes fixed in a rigid subunit. There will be just one contribution $\epsilon_{2,0}(j)$ from a fragment with cylindrical symmetry, and two, $\epsilon_{2,0}(j)$ and $\epsilon_{2,2}(j)$, from a fragment with lower symmetry, provided that the principal axes for $\epsilon(j)$ are known.

For example, the $\epsilon_{2,p}(j)$ values for the rigid fragments in the mesogens 4-*n*-alkyl-4'-cyanobiphenyl (NCBs) (5) are as given in Table 1.

Note that, since the two rings share a common symmetry axis, then $\epsilon_{2,0}(\mathbf{R}^1) = \epsilon_{2,0}(\mathbf{R}^2)$.

4.2 The Correlated Fragment or Chord Model

The independent fragment model does not always produce an $\epsilon(\{\phi\})$ matrix which accounts correctly for the shape of the conformer. This is illustrated in Figure 2, which shows two conformations of an alkane which give identical $\epsilon(\{\phi\})$ matrices, but which would be expected to have different matrices because of their different shapes.

Figure 2 The conformations of decane which have different shapes, but which have identical interaction tensor elements $\epsilon_{2,m}(\{\phi\})$ when these are constructed as the sum of individual, independent C–C bond contributions. (From Photinos et al.⁸)

To overcome this deficiency in the AP method, Photinos et al.⁸ added terms to $U_{\text{ext}}(\beta, \gamma, \{\phi\})$ which depend on the relative orientations of different fragments. They considered fragments with cylindrical symmetry, such as C–C bonds, and proposed a potential of mean torque of the form

$$U_{\text{ext}}(\beta, \gamma, \{\phi\}) = - \sum_i w_i P_2(\cos \theta_i) - \sum_{i \neq j} w_{ij} P_{ij}(s^i, s^{i+j}) \quad (21)$$

where

$$P_2(\cos \theta_i) = \frac{1}{2}(3 \cos^2 \theta_i - 1) \quad (22)$$

and

$$P_{ij}(s^i, s^{i+j}) = \frac{1}{2}(3 \cos \theta_i \cos \theta_{i+j} - s^i \cdot s^{i+j}) \quad (23)$$

where θ_i is the angle between the i th C–C bond and the director, s^i and s^{i+j} are unit vectors along the i th and $(i+j)$ th C–C bonds. The w_i and w_{ij} terms are the interaction strengths. For the case of an alkane, the w_i are all given the same value of w_0 , and so the w_{ij} can be denoted by w_j . Note that for alkanes w_1 has a similar magnitude to w_0 , and so the second terms in equation (21) should not be regarded as small corrections to the first.

Photinos et al.⁸ also showed that an equivalent representation for $U_{\text{ext}}(\beta, \gamma, \{\phi\})$ is obtained by considering not bonds but chords c^i joining the midpoints of adjacent bonds, as shown in Figure 3. Note that the first and last bonds are denoted by unit vectors t^1 and t^{N-1} . In this chord representation, and including only nearest neighbor chord correlations (corresponding to bond correlations of next-nearest neighbors):

$$U_{\text{ext}}(\beta, \gamma, \{\phi\}) = - \left\{ g_0 \sum_{i=1}^{N-2} P(c^i, c^i) + g_1 \sum_{i=1}^{N-3} P(c^i, c^{i+1}) + w_0^t [P(t^1, t^1) + P(t^{N-1}, t^{N-1})] + w_1^t [P(t^1, c^1) + P(t^{N-1}, c^{N-2})] \right\} \quad (24)$$

where $g_0 = [2 \sin^2(\text{CCC}/2)]w_0$, $w_0^t = \frac{1}{2}w_0$, $w_1^t = \sin(\text{CC C}/2)w_1$, and $g_1 = 2 \sin^2(\text{CCC}/2)w_1$. The terms involving g_1 and

Table 1 The $\epsilon_{2,p}(j)$ Values for the Rigid Fragments of the Mesogen (5)

Fragment	$\epsilon_{2,p}(j)$
	$\epsilon_{2,0}(\mathbf{R}^1), \epsilon_{2,2}(\mathbf{R}^1)$
	$\epsilon_{2,0}(\mathbf{R}^2), \epsilon_{2,2}(\mathbf{R}^2)$
All C(i)–C(j)	$\epsilon_{2,0}(\text{CC})$
All C–H bonds	$\epsilon_{2,0}(\text{CH})$

Figure 3 The unit vectors used in the chord model. (From Photinos et al.⁸)

w_1^t allow for correlations between chords, and in the simplest scheme these are set to zero, w_1 is set equal to w_0 , and the resulting uncoupled chord model has

$$U_{\text{ext}}(\beta, \gamma, \{\phi\}) = - \left\{ g_0 \sum_{i=1}^{N-2} P(c^i, c^i) + w_0^t [P(t^1, t^1) + P(t^{N-1}, t^{N-1})] \right\} \quad (25)$$

4.3 Shape Models

The mean field experienced by a molecule in a liquid crystalline phase will depend on its shape, and the chord model was introduced to improve the correlation between $U_{\text{ext}}(\beta, \gamma, \{\phi\})$ and a conformer's shape. More direct methods have been proposed for constructing shape dependent potentials of mean torque. Thus Ferrarini et al.⁹ have proposed a second rank shape tensor, $T^{(2,m)}(\{\phi\})$ which is constructed as

$$T^{(2,m)}(\{\phi\}) = - \int_S dS C_{2,m}^*(\theta, \chi) \quad (26)$$

where θ and χ are the spherical polar angles made by $\mathbf{n}_s$, the normal to the surface of the molecule at a given point. The molecular surface is constructed by placing spheres with van der Waals radii on each atom. The potential of mean torque is now

$$U_{\text{ext}}(\beta, \gamma, \{\phi\}) = -\epsilon \sum_m T^{(2,m)*}(\{\phi\}) C_{2,m}(\beta, \gamma) \quad (27)$$

where ϵ is the only adjustable parameter.

5 APPLICATIONS

Studies by NMR of flexible molecules in liquid crystalline phases are of two kinds: those of the mesogens themselves, when the motive may be to characterize the orientational order, and a conformational model is assumed, and of nonmesogenic solutes, when the main motive is to investigate the conformational distribution. Some examples are given here to illustrate both these types of investigation, but most emphasis is given to studies aimed at determining the conformational distribution.

5.1 Single Rotors

Biphenyl is an example which has been studied by both the AP and maximum entropy (ME) methods.¹⁰ The data are the set of interproton dipolar couplings obtained by analyzing the very complex proton spectrum. The maximum entropy method gives a distribution $P_{\text{LC}}(\phi)$ peaked at 34° , whilst the AP method gives a similar shape for $P_{\text{LC}}(\phi)$ and $P_{\text{iso}}(\phi)$, with a maximum at 38° . It is important to note too that the data can be fitted to jumps between a single set of symmetry related conformations, corresponding to an interring angle of 32° . Clearly, for this molecule the data cannot discriminate between the conformational analysis methods, since all three results can be considered reasonable. Such agreement is not always found. For example, for benzyl chloride,¹¹ again with interproton dipolar couplings as the data, the jump model yields a structure (III) in which the C–Cl bond is at 60° to the ring plane, whilst analysis by the AP method gives the potential shown in Figure 4. The most probable structure is that with the C–Cl bond at 90° (II). Structure (I) has the C–Cl in the ring plane. Molecular orbital calculations, electron diffraction experiments, and long-range $J(\text{H}, \text{H})$ values all give (II) as the most probable structure, thus supporting the AP result rather than the one obtained with the jump model.

5.2 Two Rotors

The most interesting result to emerge from studies of molecules with two bond rotations is that it may be necessary to allow for cooperative rather than independent rotations. This was revealed by a maximum entropy analysis¹² of the $D(\text{H}, \text{H})$ values obtained for some ethoxybenzenes.¹³ Continuous distributions for rotation about the ring–oxygen bond (through ψ) and about the O–CH₂ bond (through ϕ), as shown in Figure 5, were considered, the rotation about the C–CH₃ bond being approximated as three-site jumps. The probability distribution obtained for ethoxybenzene dissolved in a nematic solvent is shown in Figure 6, and this clearly shows, through the elliptical shape of the contours, that the two rotations are cooperative.

A similar coupled rotation in anisole has been revealed by an AP analysis of dipolar couplings,¹⁴ and for this to be established it was necessary to increase the data set to include some ^{13}C – ^1H couplings by studying anisole– $^{13}\text{CH}_3$.

Figure 4 The potential functions determined using the AP method for benzyl chloride dissolved in the nematic solvents ZLI 1167 (—) and ZLI 1132 (---)¹¹

Figure 5 Ethoxybenzene

Figure 6 A contour representation of $P_{LC}(\psi, \phi)$ obtained for 4-fluoroethoxybenzene dissolved in a nematic solvent¹²

5.3 Alkanes and Alkyl Chains

As the molecules increase in size, the proton spectra become extremely complex, and it is necessary to resort to methods of spectral simplification in order to obtain interproton dipolar couplings. Thus, dipolar couplings have been obtained for a series of alkanes dissolved in nematic solvents from deuterium decoupled proton spectra obtained on 80% randomly deuterated samples (see *Liquid Crystalline Samples: Spectral Analysis*). Dipolar couplings between ^{13}C and ^1H have also been obtained for mesogenic molecules by using local field spectroscopy coupled with spinning close to the magic angle (see *Spinning Liquid Crystalline Samples* and *Liquid Crystalline Samples: Carbon-13 NMR*). A simpler approach is to study the deuterium spectra of deuterated samples, but with the disadvantage that the quadrupolar couplings obtained form a smaller set with which to test models for the conformational distribution (see *Liquid Crystalline Samples: Deuterium NMR*).

When there are several bond rotations in a molecule it becomes impracticable to sample enough points for each rotation in order to be able to characterize the functional form of the potentials by NMR. The conformational distribution in such cases is usually dramatically simplified to being only the conformers at the minima in the rotational potential (the RIS model). For alkyl chains this involves the three forms shown in Figure 7. The conformations of a chain are obtained as combinations of *trans* and *gauche* forms about each C–C bond. The energy difference between *trans* and *gauche* forms

Figure 7 *Trans* and *gauche* conformations of $\text{RCH}_2\text{CH}_2\text{R}'$ compounds

E_{tg} is the only adjustable parameter in the simplest RIS model. A term $E_{g\pm g\pm}$ is sometimes added to discriminate against conformers having $g\pm g\pm$ sequences.

The dipolar couplings obtained for the alkanes dissolved in a nematic solvent have been analyzed using different additive potential methods and the RIS model for the conformations.¹⁵ The observed and calculated D_{ij} were brought into agreement by varying the parameters defining $U_{\text{ext}}(\beta, \gamma, \{\phi\})$ (which differ for each model) and E_{tg} . The quality of the fitting is similar for all the methods used, but very different values of E_{tg} were obtained. The chord model gave an E_{tg} closest to that obtained by other methods. A better fit to the data for hexane has been obtained by increasing to nine the points sampled on each C–C bond rotational potential.¹⁶

5.4 Mesogenic Molecules

The simplest mesogen, 4-methoxy-4'-cyanobiphenyl (1OCB) contains 11 protons and has a very complex proton spectrum, but one which has been analyzed,¹⁷ and the data used to investigate the conformational distribution. Similar studies have been made of more complex mesogens, when dipolar couplings between protons in fragments of the molecules have been obtained by partial deuteration followed by deuterium decoupling.^{18–20} Several mesogens have been studied by ^{13}C NMR using the technique of spinning close to the magic angle combined with dipolar local field spectroscopy (see *Liquid Crystalline Samples: Carbon-13 NMR*). The RIS model has been used for the conformational distributions in these studies, and this has also been the model adopted to interpret the quadrupole splittings obtained from deuterium NMR. The objectives in most of these studies has been primarily to show that the particular models used for constructing $U_{\text{ext}}(\beta, \gamma, \{\phi\})$, together with the RIS model, are capable of fitting the data.^{21–23} It is not yet clear which of the methods of constructing the potential of mean torque is the best, but there is now a clear consensus that molecular interpretations of liquid crystal properties must take into account bond rotational motion, and that, conversely, it is possible for a conformational distribution to change quite substantially on changing from an isotropic to a liquid crystalline phase.^{7,22,23}

1 INTRODUCTION

The NMR spectra of liquid crystalline samples are like those of solids in that anisotropic interactions, such as dipole–dipole and nuclear electric quadrupole–electric field gradient interactions, contribute to the spectrum. The spectra are also similar to those from isotropic liquids in that relaxation rates are small, leading to narrow lines for individual resonances. These features of the spectra have ensured that NMR has become the best method for studying the structure, orientational order and dynamics of molecules in liquid crystalline phases.

The general factors which determine the form taken by the spectra of nuclei in liquid crystalline phases are discussed here. This includes a discussion of the principal contributions to the Hamiltonian, and the relationship with molecular properties of the parameters which can be obtained by analyzing the spectra. A general outline will be presented of the factors which determine relaxation rates, and this is followed by a brief discussion of the spectra observed for protons, carbon-13 and deuterium nuclei, which are the three most important nuclei for studying liquid crystalline samples.

More details of the NMR of liquid crystalline samples can be found in Emsley,¹ Dong,² and Emsley and Lindon,³ and in other articles in this Encyclopedia (see Related Articles)

2 MOTIONAL AVERAGING IN LIQUID CRYSTALLINE SAMPLES

The molecules in liquid crystalline phases are moving at speeds comparable with those in isotropic liquids, with similar viscosities. This means that the spectra depend on interactions averaged over this molecular motion, and so to understand the form taken by the spectra, and to appreciate their information content, it is necessary to consider the nature of the averaging process in some detail.

Figure 1 (a) Distribution of the symmetry axes of rigid, cylindrically symmetric molecules about the director n_i . (b) The un-normalized probability $f(\beta)$ that the symmetry axis is at an angle between β and $\beta + d\beta$

2.1 The Liquid Crystal Director

Although the molecular motion is rapid, it is not random, in that at any point in the sample the molecules have a preferred orientation. The simplest phases, which are referred to as ‘uniaxial,’ are such that there is $D_{\infty h}$ symmetry at this point for the distribution of the molecules about a unit vector n_i known as the ‘local director.’ To illustrate this concept the molecules, for simplicity, but without sacrificing generality, are assumed to be rigid and cylindrical in shape and symmetry. In this case the distribution of the cylinder axes about n_i are shown in Figure 1(a), and Figure 1(b) shows the probability $f(\beta)$ that the axes are at an orientation between β and $\beta + d\beta$ with respect to n_i . This singlet, orientational distribution function is symmetrical about $\beta = 90^\circ$. The direction of n_i varies continuously and randomly throughout a macroscopic sample, unless there is some external constraint acting, but $f(\beta)$ is independent of the position in the bulk sample. There is, therefore, microscopic, but not macroscopic, orientational order in an unconstrained liquid crystalline sample.

There are also liquid crystalline phases in which the symmetry about the local directors is D_{2h} , and it is now necessary to specify three unit vectors directed along axes X , Y , and Z fixed at the i th point.

Figure 2 Deuterium spectrum observed for D_2O in a liquid crystalline sample for uniform alignment of the directors along the applied field B_0 (a), and with the directors uniformly distributed at all orientations to B_0 (b)

2.2 Averaging Produced by Motion Relative to the Director

When molecular motion is faster than the anisotropy ΔT in some nuclear spin interaction, then the spectrum depends on T_{XX} , T_{YY} , and T_{ZZ} , the components of the tensor in the director frame. The spectrum is also affected by the orientation of the static, applied magnetic field, B_0 , in the local director frames. For example, for a uniaxial phase, the deuterium spectrum produced by a group of chemically equivalent deuterons consists of a pair of lines whose separation $\Delta\nu(\theta)$ depends on the angle θ between the director and B_0 . Thus, for a sample in which all the directors are at a single value of θ , then

$$\Delta\nu(\theta) = \Delta\nu(0^\circ)(3 \cos^2 \theta - 1)/2 \quad (1)$$

where $\Delta\nu(0^\circ)$ is the splitting for $\theta = 0^\circ$. A spectrum of this kind is shown in Figure 2(a). If the directors do not adopt a single value of θ but are distributed uniformly in space, then the spectrum is a superposition of doublets, weighted according to the probability distribution for θ . This is identical in form to the spectrum observed for deuterium in polycrystalline solid samples, except for a reduction in the overall width of the spectrum (see Section 8), as shown in Figure 2(b). The spectrum observed from a liquid crystalline sample therefore changes dramatically depending on the how the directors are distributed in the magnetic field.

2.3 Alignment of Directors by a Magnetic Field

The local directors n_i of a uniaxial phase can be aligned along a common direction to create macroscopic order by applying an electric field, by confining the sample between glass plates, by spinning the sample, or by application of a magnetic field. The creation of a uniformly aligned biaxial phase requires the application of two constraints.

The alignment by a magnetic field is obviously of greatest importance for NMR experiments, although the other methods do have their uses. Magnetic field alignment occurs because the field exerts a force on the molecules, which depends upon the magnitude of χ^{mol} , the magnetic susceptibility tensor for each molecule, and on the extent of the correlations between the orientations of the molecules relative to their local director. Thus, considering a single, rigid, cylindrically symmetric molecule at a fixed orientation β_i with respect to n_i

in a uniaxial phase, the contribution F_i to the magnetic energy is

$$F_i = -\frac{1}{4}\Delta\chi^{\text{mol}}B_0^2(3 \cos^2 \beta_i - 1) \quad (2)$$

F_i is a minimum for $\Delta\chi^{\text{mol}}$ positive when $\beta_i = 0^\circ$, and the molecule will want to adopt this orientation. However, collisions between molecules tend to produce an isotropic distribution of β_i , and for a normal liquid this randomizing effect is much larger than the orienting effect of B_0 . This means that $\bar{P}_2$, the average of the function $P_2(\cos \beta_i)$ over all the molecules, is very small ($\approx 10^{-5}$), and the samples are essentially isotropic at fields less than about 9 T. Note, however, that the effect is large enough to produce dipolar or quadrupolar splittings in higher fields when $\Delta\chi^{\text{mol}}$ is large (see *Magnetic Field Induced Alignment of Molecules*).

A different situation prevails in a liquid crystalline phase, since now there is a net alignment of the molecules along the local directors, and the magnetic torque acting on each director becomes

$$F(\alpha_j) = -\Delta\chi^{\text{mol}}\bar{P}_2(3 \cos^2 \alpha_j - 1)B_0^2/6 \quad (3)$$

where α_j is the angle between the director n_j and B_0 . This magnetic force is now large enough relative to the thermal energy that the probability $f(\alpha)$ that a director lies between α and $\alpha + d\alpha$ with respect to B_0 is sharply peaked at $\alpha = 0^\circ$ when $\Delta\chi^{\text{mol}}$ is positive, and at $\alpha = 90^\circ$ when $\Delta\chi^{\text{mol}}$ is negative. This means that virtually complete alignment of the directors can be obtained for uniaxial phases in the magnets of NMR spectrometers.

The alignment is opposed by the sample's viscosity, and there may also be a conflict with the spatial organization present in smectic, discotic, chiral, and some amphiphilic phases. In practice, alignment occurs rapidly and completely for nematic samples as soon as a sample has been placed in the magnet. Phases with spatial order behave in a more complex manner. It is usually possible, however, to obtain uniform director alignment in uniaxial smectic phases by cooling the sample from an aligned phase

3 THE TIME-AVERAGED HAMILTONIAN $\hat{\mathcal{H}}$

3.1 The General Form

A full discussion of the form taken by the Hamiltonian has been presented by Veracini,⁴ and here the discussion is restricted to presenting results and discussing their implications.

A nuclear spin Hamiltonian can be written using either Cartesian, or irreducible spherical tensors. Both will be used here, but at first the spherical tensor form is employed because it is particularly useful for showing which components are nonzero for different symmetries, either of the phase or the molecules. Thus, in this notation the general form for the Hamiltonian is

$$\hat{\mathcal{H}} = \sum_{\lambda} \sum_{m=-L}^{+L} (-1)^m T_{\lambda}^{(L,m)} \hat{A}_{\lambda}^{(L,-m)} \quad (4)$$

λ denotes the different interactions contributing to $\hat{\mathcal{H}}$; $T_\lambda^{(L,m)}$ are the irreducible, spherical components of the tensor representing the λ th interaction, and $\hat{A}_\lambda^{(L,m)}$ is the appropriate nuclear spin operator. NMR experiments are usually done with magnetic fields which are sufficiently strong that the field direction is a unique axis of quantization for the nuclear spin angular momentum (but note that this will not be the case for some quadrupolar nuclei, see *Quadrupolar Interactions*). Confining the discussion to this high-field case means that the uniaxial symmetry about $\mathbf{B}_0$ restricts the terms in $\hat{\mathcal{H}}_\lambda$ to those involving only the components of the tensors along $\mathbf{B}_0$, that is those with $m = 0$, and since L is either 0 or 2, then

$$\hat{\mathcal{H}}_\lambda = \sum_\lambda T_\lambda^{(0,0)} \hat{A}_\lambda^{(0,0)} + \sum_\lambda T_\lambda^{(2,0)} \hat{A}_\lambda^{(2,0)} \quad (5)$$

The spherical tensor notation clearly shows that, in general, there are rotationally invariant contributions to $\hat{\mathcal{H}}_\lambda$ (those with $L = 0$) and anisotropic contributions (those with $L = 2$).

3.2 The Effect of Director Orientation on $\hat{\mathcal{H}}_\lambda$

The rotationally invariant (scalar) contributions are unaffected by director orientation, and so too are the spin operators $\hat{A}_\lambda^{(2,0)}$. The anisotropic contributions, $T_\lambda^{(2,0)}$ are related to $T_{\lambda d}^{(2,0)}$, the components in a coordinate frame fixed on the director by

$$T_{\lambda d}^{(2,0)} = \sum_n T_{\lambda d}^{(2,n)} D_{0,n}^{2*}(\alpha, \beta, \gamma) \quad (6)$$

where α, β , and γ are the Euler angles (defined as in Zannoni⁵) describing the orientation of $\mathbf{B}_0$ in the director frame, and $D_{0,n}^{2*}(\alpha, \beta, \gamma)$ is an element of a second-rank Wigner rotation matrix. The angle α is redundant when $m = 0$, and in this case the Wigner functions can be replaced by spherical harmonics $Y_{2,n}(\beta, \gamma)$, so that

$$T_\lambda^{(2,0)} = (4\pi/5)^{1/2} \sum_n T_{\lambda d}^{(2,n)} Y_{2,n}(\beta, \gamma) \quad (7)$$

or, in a slightly more compact form, by modified spherical harmonics $C_{2,n}(\beta, \gamma)$:

$$T_\lambda^{(2,0)} = \sum_n T_{\lambda d}^{(2,n)} C_{2,n}(\beta, \gamma) \quad (8)$$

The angles β and γ are shown in Figure 3.

Choosing the director frame X, Y, Z to be the principal frame for $T_{\lambda d}$, then n is restricted to being 0 or ± 2 , and it is possible, at least in principle, to obtain both $T_{\lambda d}^{(2,0)}$ ($= \sqrt{2/3} T_{ZZ}$), and $T_{\lambda d}^{(2,2)} + T_{\lambda d}^{(2,-2)}$ ($= T_{XX} - T_{YY}$).

If the liquid crystalline phase has uniaxial symmetry about the directors, then $n = 0$, and equation (7) becomes

$$T_\lambda^{(2,0)} = \frac{1}{2} (3 \cos^2 \beta - 1) T_{\lambda d}^{(2,0)} \quad (9)$$

Figure 3 The orientation of $\mathbf{B}_0$ in the director frame XYZ

4 RELATIONSHIP BETWEEN $T_{\lambda d}^{(L,n)}$ AND COMPONENTS OF THE SAME INTERACTIONS IN A MOLECULAR FRAME $T_{\lambda \text{mol}}^{(L,m)}$

If the phase is biaxial it may be possible to obtain both $T_{\lambda d}^{(L,0)}$ and $T_{\lambda d}^{(L,\pm 2)}$, and these are related to $T_{\lambda \text{mol}}^{(L,m)}$ by

$$T_{\lambda d}^{(L,m)} = \sum_{m=-2}^2 T_{\lambda \text{mol}}^{(L,m)} \langle D_{m,n}^{2*} \rangle \quad (10)$$

where $\langle D_{m,n}^{2*} \rangle$ is the average over all molecules of $D_{m,n}^{2*}(\alpha, \beta, \gamma)$, a Wigner function describing the rotation of the molecular frame into the director frame. These averages are known as *molecular order parameters*.

4.1 Molecular Order Parameters in Different Notations

A confusing aspect of the literature on the NMR of liquid crystalline samples is the alternative ways of denoting molecular order parameters. The $\langle D_{m,n}^{2*} \rangle$ is appropriate for all phase and molecular symmetries, and should be used when the phase symmetry is less than $D_{\infty h}$.

Motional constants are averages of spherical harmonics $\langle Y_{2,m}^* \rangle$, and are useful when there is cylindrical symmetry about the directors, and similarly in this case it is appropriate to use averages of modified spherical harmonics $\langle C_{2,m}^* \rangle$.

Saue order parameters are used the most frequently, and are appropriate for uniaxial phases. They are averages of the transformation matrix elements expressed in a Cartesian molecular frame:

$$S_{\alpha\beta} = \langle (3 \cos \theta_\alpha \cos \theta_\beta - \delta_{\alpha\beta})/2 \rangle \quad (11)$$

where α and β are Cartesian axes, and $\delta_{\alpha\beta}$ is 1 if $\alpha = \beta$ and zero otherwise. If a molecule is rigid and has cylindrical symmetry, then S_{zz} is the only nonzero order parameter, where z is the symmetry axis. In this case S_{zz} is often referred to as $\bar{P}_2$.

The relationship between these order parameters is given in Table 1.

Table 1 Relationship Between Molecular Order Parameters as Averages of Wigner Functions $\langle D_{m,n}^2 \rangle$, Cartesian Functions (Saupe Order Matrix $S_{\alpha\beta}$), Modified Spherical Harmonics $\langle C_{2,m} \rangle$, and Spherical Harmonics (Motional Constants C)

$S_{\alpha\beta}$	$\langle D_{m,n}^2 \rangle$	$\langle C_{2,m} \rangle$	Motional constant
S_{zz}	$\langle D_{0,0}^2 \rangle$	$\langle C_{2,0} \rangle$	$\sqrt{(1/5)}C_{3z^2-r^2}$
$S_{xx} - S_{yy}$	$\sqrt{(3/2)}[\langle D_{0,2}^2 \rangle + \langle D_{0,-2}^2 \rangle]$	$\sqrt{(3/2)}[\langle C_{2,2} \rangle + \langle C_{2,-2} \rangle]$	$\sqrt{(3/5)}C_{x^2-y^2}$
S_{xy}	$i\sqrt{(3/8)}[\langle D_{0,2}^2 \rangle - \langle D_{0,-2}^2 \rangle]$	$i\sqrt{(3/8)}[\langle C_{2,0} \rangle - \langle C_{2,-2} \rangle]$	$\sqrt{(3/5)}C_{xy}$
S_{xz}	$-\sqrt{(3/8)}[\langle D_{0,1}^2 \rangle + \langle D_{0,-1}^2 \rangle]$	$\sqrt{(3/8)}[\langle C_{2,-1} \rangle + \langle C_{2,1} \rangle]$	$\sqrt{(3/5)}C_{xz}$
S_{yz}	$i\sqrt{(3/8)}[\langle D_{0,1}^2 \rangle - \langle D_{0,-1}^2 \rangle]$	$i\sqrt{(3/8)}[\langle C_{2,1} \rangle - \langle C_{2,-1} \rangle]$	$\sqrt{(3/5)}C_{yz}$

4.2 Relationship Between Order Parameters and Molecular Orientation

The $\langle D_{m,n}^{2*} \rangle$ are related to, but are not a complete description of, the orientational order of the molecules in a liquid crystalline phase. Consider a molecule of general shape, and which may also have internal motional freedom. Fixing axes in a rigid part of the molecule, then the singlet orientational distribution function, $f(\alpha, \beta, \gamma)$, is defined as the probability that the director frame is at an orientation between α, β, γ and $\alpha + d\alpha, \beta + d\beta, \gamma + d\gamma$. This is the generalization of the function $f(\beta)$, whose shape is shown in Figure 1, and which was introduced for the special case of a cylindrically symmetric molecule in a uniaxial phase.

The Wigner functions $D_{k,p}^L(\alpha, \beta, \gamma)$ form a complete, orthogonal set, and so $f(\alpha, \beta, \gamma)$ is conveniently expressed as

$$f(\alpha, \beta, \gamma) = \sum_{L, \text{even}}^{\infty} \sum_{k=-L}^L \sum_{p=-L}^L f_{Lkp} D_{k,p}^L(\alpha, \beta, \gamma) \quad (12)$$

with the expansion coefficients f_{Lkp} given by:

$$f_{Lkp} = [(2L+1)/8\pi^2] \langle D_{k,p}^{L*} \rangle \quad (13)$$

Thus, the second-rank order parameters which appear in equation (10) are only a small subset of the infinite set required to characterize $f(\alpha, \beta, \gamma)$. Nonetheless, they form the largest set of order parameters which are obtained easily from experimental data, and they are the principal data used to test theoretical models for $f(\alpha, \beta, \gamma)$.

4.3 Second-Rank Order Parameters and Phase and Molecular Symmetry

Most liquid crystal phases have either $D_{\infty h}$ symmetry about the directors, and are described as being uniaxial, or D_{2h} symmetry, and are biaxial phases. All symmetries are possible for the molecules in these phases. Mesogenic (a term used to describe a molecule which may form an ordered phase) molecules in liquid crystalline phases are invariably flexible to some extent, because of bond rotational motion. It is important to note the effect that this flexibility has on symmetries. Phase symmetry is unaffected by the flexibility, but for molecules the internal motion introduces additional complexity to the relationship between spectral and molecular properties. This is dealt with in detail elsewhere (see *Liquid Crystalline Samples: Structure of Nonrigid Molecules*), but it should be noted

that flexibility does not lead to any simplifications regarding molecular symmetry. In particular, it is not permissible to invoke a time-averaged structure with a higher symmetry than the individual conformations that the molecule can adopt. Unfortunately this is not always recognized. *Local order matrices*, which are for axes fixed in a rigid subunit of a molecule, are simplified by internal motion. For example, for axes fixed in the fragment 1, the local order matrix has three independent, nonzero elements S_{zz} , $S_{xx} - S_{yy}$, and S_{xz} if the A and B groups are stationary and in the xz plane. Rotation of only one of the groups A or B does not produce any simplification in S, but uncorrelated rotation of both groups through angles ϕ_1 and ϕ_2 , each with potentials which have at least twofold symmetry, renders S_{xz} zero.

Molecular flexibility can lead to an increase in spin permutation symmetry, and hence to simpler spectra. The simplifications are similar to those produced for isotropic liquid samples, but not identically so. These aspects are discussed by Emsley and Lindon.³

In interpreting the spectral parameters obtained from the analysis of the spectrum it is necessary to consider four different cases. The discussion here is confined to the case of rigid molecules, and rigid fragments of flexible molecules.

4.3.1 A Biaxial Molecule in a Biaxial Phase

A biaxial molecule has a point group symmetry lower than C_3 . All the terms in equation (10) are nonzero. However, choosing the reference frame on the director to be a principal frame then n is 0 or ± 2 . Similarly, if the molecular frame can be chosen to be a principal frame for the interaction tensor, or for the order matrix in the case of a rigid molecule or rigid molecular fragment, then m is again restricted to 0 and ± 2 .

4.3.2 A Uniaxial Molecule in a Biaxial Phase

For molecules which have C_3 symmetry or higher, m must be zero and equation (10) becomes

$$T_{\lambda d}^{(L,n)} = T_{\lambda, \text{mol}}^{(2,0)} \langle D_{0,n}^{2*} \rangle \quad (14)$$

A reference frame fixed on the director exists in which the only nonzero values of $\langle D_{0,n}^{2*} \rangle$ have $n = 0$ or ± 2 . The location of this

principal director frame from the results of NMR experiments may, however, pose a problem.

4.3.3 A Biaxial Molecule in a Uniaxial Phase

Now n must be zero and

$$T_{\lambda d}^{(L,0)} = \sum_{m=-2}^2 T_{\lambda, \text{mol}}^{(L,m)} \langle D_{m,0}^{2*} \rangle \quad (15)$$

Location of the principal axes of $\langle D_{m,0}^{2*} \rangle$ is possible if the molecule has two orthogonal planes of symmetry. If the molecule has one mirror plane only, then one axis is identified with the normal to the plane, and location of the other two axes requires the measurement of at least three, independent, averaged interactions, such as dipolar or quadrupolar splittings.

4.3.4 A Uniaxial Molecule in a Uniaxial Phase

Now both m and n must be zero, so that equation (10) becomes

$$T_{\lambda d}^{(L,0)} = T_{\lambda, \text{mol}}^{(2,0)} \langle D_{0,0}^{2*} \rangle \quad (16)$$

which can be simplified to

$$T_{\lambda d}^{(L,0)} = T_{\lambda, \text{mol}}^{(2,0)} \langle (3 \cos^2 \beta - 1)/2 \rangle \quad (17)$$

5 INDIVIDUAL CONTRIBUTIONS TO $\hat{\mathcal{H}}$

The discussion has so far been kept general, and the spherical tensor notation has been appropriate since this facilitates the identification of the effects of director orientation, and phase, and molecular symmetries. But it is more useful to use a Cartesian frame when considering individual contributions $\hat{\mathcal{H}}_{\lambda}$. Thus, the spin operators are best represented in terms of $\hat{I}_{zi}$ and the raising and lowering operators, $\hat{I}_{\pm i}$, where z is the direction of $\mathbf{B}_0$.

5.1 The Zeeman Interaction $\hat{\mathcal{H}}_Z$

$$\hat{\mathcal{H}}_Z = (B_0/2\pi) \sum_i \gamma_i \hat{I}_{zi} (1 - \tilde{\sigma}_{zzi}) \quad (18)$$

Note that we differ from Veracini⁴ in that $\tilde{\sigma}_{zzi}$ is the component along $\mathbf{B}_0$ of the partially averaged (symbolized by tilde) total shielding tensor at the i th site. Thus,

$$\tilde{\sigma}_{zzi} = \sigma_i^{\text{iso}} + \sigma_{zzi}^{\text{aniso}} \quad (19)$$

The isotropic, scalar term σ_i^{iso} contains contributions from the components $\sigma_{\alpha\beta}$ of the shielding tensor of a nucleus in an isolated molecule, and it is these which are most

easily calculated by theoretical models, but there are also contributions from intermolecular effects, and from the magnetic shielding produced by the shape of the sample and the bulk magnetic susceptibility (see *Anisotropy of Shielding and Coupling in Liquid Crystalline Solutions*).

The relationship between $\tilde{\sigma}_{zzi}$ and $\sigma_{\alpha\beta i}$, the components of the shielding tensor in a molecular frame for a uniaxial phase with the director aligned along $\mathbf{B}_0$, is

$$\begin{aligned} \tilde{\sigma}_{zzi} = & \sigma_i^{\text{iso}} + \frac{2}{3} S_{aa} \{ \sigma_{aai} - \frac{1}{2} (\sigma_{bbi} + \sigma_{cc i}) \} \\ & + \frac{1}{3} (S_{bb} - S_{cc}) (\sigma_{bbi} - \sigma_{cc i}) \end{aligned} \quad (20)$$

The molecular axes a , b , and c are either principal axes for the order matrix $\mathbf{S}$, or for the shielding tensor σ .

5.2 The Indirect Spin-Spin Interaction $\hat{\mathcal{H}}_J$

$$\begin{aligned} \hat{\mathcal{H}}_J = & \sum_{i < j} \{ J_{ij}^{\text{iso}} [\hat{I}_{zi} \hat{I}_{zj} + \frac{1}{2} (S_{bb} - S_{cc}) (\hat{I}_{+i} \hat{I}_{-j} + \hat{I}_{-i} \hat{I}_{+j})] \\ & + J_{zzij}^{\text{aniso}} [\hat{I}_{zi} \hat{I}_{zj} - \frac{1}{4} (S_{bb} - S_{cc}) (\hat{I}_{+i} \hat{I}_{-j} + \hat{I}_{-i} \hat{I}_{+j})] \} \end{aligned} \quad (21)$$

The scalar coupling term J_{ij}^{iso} is, in principle, affected by the bulk medium, but in practice such effects are negligible for the lighter nuclei (see *Anisotropy of Shielding and Coupling in Liquid Crystalline Solutions*), so that it is identical to the value observed for the isotropic phase of the sample.

The relationship between J_{zzij}^{aniso} and $J_{\alpha\beta ij}$, the components of the spin-spin coupling tensor in a molecular frame for a uniaxial phase with the director aligned along $\mathbf{B}_0$, is

$$\begin{aligned} J_{zzij}^{\text{aniso}} = & \frac{2}{3} S_{aa} \{ J_{aaij} - \frac{1}{2} (J_{bbij} + J_{ccij}) \} \\ & + \frac{1}{3} (S_{bb} - S_{cc}) (J_{bbij} - J_{ccij}) \end{aligned} \quad (22)$$

The molecular axes a , b , and c are either principal axes for the order matrix $\mathbf{S}$, or for the spin-spin coupling tensor $\mathbf{J}_{ij}$.

5.3 The Direct, Dipole-Dipole Interaction $\hat{\mathcal{H}}_D$

$$\hat{\mathcal{H}}_D = \sum_{i < j} 2\tilde{D}_{zzij} [\hat{I}_{zi} \hat{I}_{zj} - \frac{1}{4} (\hat{I}_{+i} \hat{I}_{-j} + \hat{I}_{-i} \hat{I}_{+j})] \quad (23)$$

This interaction is totally anisotropic. Note that the operators occur in an identical form to those involving J_{zzij}^{aniso} in equation (21), so that the two interactions are spectroscopically indistinguishable. This has important consequences when attempting to obtain the magnitudes of J_{zzij}^{aniso} (see *Anisotropy of Shielding and Coupling in Liquid Crystalline Solutions*), or when using $\tilde{D}_{zzij}$ to investigate molecular structure (see *Structure of Rigid Molecules Dissolved in Liquid Crystalline Solvents*).

The rapid translational and rotational motion of the molecules averages intermolecular contributions to $\tilde{D}_{zzij}$ to zero, in contrast to a solid sample where intermolecular terms lead to very broad resonances even in single crystal

samples. This means that the individual resonances in a liquid crystalline, dipolar coupled spectrum, such as from protons, have widths which range from being of the order of 1 Hz for small solute molecules, to about 100 Hz for the mesogenic molecules. For a totally rigid molecule in a uniaxial phase with the directors aligned along $\mathbf{B}_0$, the value of $\tilde{D}_{zzi}$ is related to the magnitude of the internuclear vector $\mathbf{r}_{ij}$, and the angles $\theta_{ij\alpha}$ that this vector makes with molecular fixed axes by

$$\begin{aligned}\tilde{D}_{zzi} = & -(K_{ij}/r_{ij}^3)[S_{aa}(3\cos^2\theta_{ija} - 1) \\ & + (S_{bb} - S_{cc})(\cos^2\theta_{ijb} - \cos^2\theta_{ijc}) \\ & + 4S_{ab}\cos\theta_{ija}\cos\theta_{ijb} + 4S_{ac}\cos\theta_{ija}\cos\theta_{ijc} \\ & + 4S_{bc}\cos\theta_{ijb}\cos\theta_{ijc}]\end{aligned}\quad (24)$$

with

$$K_{ij} = (\mu_0/4\pi)h\gamma_i\gamma_j/8\pi^2 \quad (25)$$

The molecular axes a , b , and c are not special. The number of terms in equation (24) can be reduced if any of the principal axes of $\mathbf{S}$ can be identified from the symmetry of the molecule. The effects of small amplitude vibrational motion is discussed elsewhere in this Encyclopedia (see *Structure of Rigid Molecules Dissolved in Liquid Crystalline Solvents*).

5.4 The Nuclear Electric Quadrupole–Electric Field Gradient Interaction $\hat{\mathcal{H}}_Q$

The general case of a quadrupole interaction comparable with the Zeeman term is complex because the magnetic field direction is not a unique axis of quantization of the nuclear spin angular momentum (see *Quadrupolar Interactions*). Most studies on liquid crystalline samples involve the much simpler case where the quadrupolar interaction is much smaller than the Zeeman term, and the Hamiltonian only for this situation is given here. In this case,

$$\hat{\mathcal{H}}_Q = \sum_i \{\tilde{q}_{zzi}/[4I_i(2I_i - 1)]\}[3\hat{I}_{zi}^2 - I_i(I_i + 1)] \quad (26)$$

The term $\tilde{q}_{zzi}$ is given by:

$$\tilde{q}_{zzi} = (eQ_i\tilde{V}_{zzi})/h \quad (27)$$

where eQ_i is the nuclear electric quadrupole moment of nucleus i , and $\tilde{V}_{zzi}$ is the partially averaged component of the electric field gradient tensor measured at the nucleus, and in the direction of $\mathbf{B}_0$. Note that $\mathbf{q}$ is often used rather than χ to denote the quadrupole tensor, since this avoids confusion with the magnetic susceptibility tensor, which is also usually represented by χ .

The tensor $\mathbf{q}$ is purely anisotropic, which means that the values of $\tilde{q}_{zzi}$ are particularly useful for probing the orientational order in liquid crystalline samples.

The relationship between $\tilde{q}_{zzi}$ and $\tilde{q}_{\alpha\beta i}$, the components in a molecular frame, for an uniaxial phase with the directors aligned along $\mathbf{B}_0$, is

$$\tilde{q}_{zzi} = q_{aai}[S_{aa} + \frac{1}{3}\eta_i(S_{bb} - S_{cc})] \quad (28)$$

where $q_{zzi} > q_{bbi} > q_{cci}$, and

$$\eta_i = (q_{bbi} - q_{cci})/q_{aai} \quad (29)$$

6 RELAXATION RATES

Relaxation rates depend upon time–correlation functions $g_{mm',\lambda\lambda'}(t)$, which depend on $\hat{\mathcal{H}}_\lambda(t)$ according to

$$g_{mm',\lambda\lambda'}(t) = \langle \hat{\mathcal{H}}_\lambda(\tau)\hat{\mathcal{H}}_{\lambda'}(t + \tau) \rangle - \delta_{mm',\lambda\lambda'}\hat{\mathcal{H}}_\lambda\hat{\mathcal{H}}_{\lambda'} \quad (30)$$

The angle brackets denote an average over both τ and the ensemble; $\delta_{mm',\lambda\lambda'}$ is zero unless $m = m'$ and $\lambda = \lambda'$. To understand what causes relaxation, and what can be learned from measuring relaxation rates, it is necessary to examine the contributions to $\hat{\mathcal{H}}(t)$, and to discuss what causes the time dependence. The discussion here will not be comprehensive, but will concentrate on the dominant relaxation mechanisms for nuclei in most liquid crystalline phases. Firstly, an overview is given of the sources of the time dependences, since it is the characterization of these that is the main aim of studies of relaxation rates. In later sections, the particular relaxation mechanisms which are usually dominant for protons, carbon-13, and deuterium are discussed, together with the form taken by their spectra.

6.1 Dynamic Processes Affecting Relaxation Rates in Liquid Crystalline Samples

The dynamic processes are discussed in order of their prevalence rather than their importance in determining the relaxation rate.

6.1.1 Whole Molecule Rotation and Translational Diffusion

Such motion is always present in a liquid. The molecules which form liquid crystalline phases are always strongly anisotropic in shape, so that their rotational motion is also strongly anisotropic. In addition, the dynamics are affected by the orientational and spatial order which is present. Thus, the effect of increasing orientational order alone is to decrease the spin–lattice relaxation rate R_1 , and to increase the spin–spin relaxation rate R_2 . A second consequence is that $R_1 \neq R_2$, even when motion is fast, in contrast with isotropic liquid samples.

Translational diffusion modulates intermolecular dipolar interactions, and may be an important relaxation mechanism for protons in all liquid crystalline phases. There can also be a coupling between translational and rotational motion in phases with spatial order (see *Liquid Crystalline Samples: Relaxation Mechanisms*). Thus, in smectic, or similar amphiphilic and discotic phases, translation moves molecules between regions with different extents of rotational freedom, and in chiral phases the diffusion along the helical director configuration present in these phases induces a rotational motion of the molecules.

6.1.2 Internal Motion

All the molecules which have been found to form liquid crystalline phases have some internal rotational freedom. In

fact, most contain one or more alkyl chains, which are always conformationally mobile in liquid crystalline phases. The effect on relaxation rates has been demonstrated most convincingly using deuterium (see *Liquid Crystalline Samples: Deuterium NMR*) and carbon-13 NMR.

The combination of the whole-molecule rotation and the internal rotational motion in any liquid phase presents a very complex dynamics problem, particularly when it is recognized that these two motions are probably strongly correlated in molecules as complex as mesogens. It is not surprising, therefore, that attempts to extract quantitative information from relaxation rates have used major simplifying assumptions in order to render the problems tractable. The most sophisticated models that have been used are those developed by Nordio and his colleagues, which take into account the continuous diffusive nature of both whole-molecule and internal bond rotational motions in the presence of an anisotropic, mean field ordering potential (see *Liquid Crystalline Samples: Relaxation Mechanisms*). Dong and his colleagues have simplified the models by assuming a jump motion for the rotations about C–C bonds in alkyl chains, which is assumed to be independent of the whole molecule motion (see *Liquid Crystalline Samples: Deuterium NMR*). Most investigators, however, have interpreted relaxation data, particularly those obtained from amphiphilic systems, by using much simpler models.

Investigations of the dynamics of molecules in liquid crystalline phases by computer simulations are just beginning to be practicable, and undoubtedly will play an important role both in testing existing theoretical models and in developing new ones.

6.1.3 Director Fluctuations

The orientation of the local directors $\mathbf{n}_i$ is time-dependent. This collective molecular motion would be quenched if a sufficiently large magnetic field were applied, but these fields are several orders of magnitude greater than those in use for NMR, so that fluctuations in the uniformly aligned samples still occurs (or indeed when either surface or electric field alignment is used).

Director fluctuations produce modulations in the components along $\mathbf{B}_0$ of all the anisotropic interactions contributing to the Hamiltonian, and so in principle will produce a contribution to relaxation rates. The only question is how large is this contribution compared with other relaxation mechanisms, and can its effect be separated from them? There does appear to be some confusion in the literature on the importance of director fluctuations as a relaxation mechanism, and an attempt is made here to clarify the position in the light of the available experimental evidence, and the current theories.

The characteristic signature for the effect produced by director fluctuations on relaxation rates is the frequency dependence of R_1 . Thus, the value of R_1 for nuclei in an isotropic liquid sample, whose relaxation stems from rotational motion, is expected to depend approximately on ω_0^{-2} , where ω_0 is the Larmor frequency, when the rotational motion is slow, and becomes independent of frequency when the motion is fast. The simplest model⁶ for R_1^{DF} , the contribution to relaxation from director fluctuations, predicts a dependence on $\omega_0^{-1/2}$. The frequency dependence of R_1 for all the protons in several liquid crystalline samples has been obtained by the field

cycling technique (see *Field Cycling Experiments*), and there is clearly a change from a region where the $\omega_0^{-1/2}$ dependence holds approximately, to one where R_1 varies as ω_0^{-2} . The region where director fluctuations dominate for protons is well below that used in conventional NMR spectrometers, but these experiments do not rule out a possible contribution to R_1 at higher Larmor frequencies, but of smaller magnitude than that from whole-molecule and internal motion. The conclusion from the field cycling data is that R_1^{DF} is of minor importance for relaxation rates for all nuclei in mesogenic molecules obtained above, say, 10 MHz. This is not to say, however, that R_1^{DF} can be always neglected at such frequencies, and it remains to be established just how large this term is for particular mesogens.

The experiments on proton relaxation in mesogens have the disadvantage that the proton spectrum cannot be resolved into peaks from individual protons, so that the value of R_1 obtained by experiment is an average for a set of strongly dipolar-coupled spins, and that proton relaxation may also be affected by a number of mechanisms in addition to director fluctuations, such as internal as well as whole-molecule rotational motion, and intermolecular contributions may also be important. This problem is removed by studying the relaxation rates of deuterons in dissolved, rigid solutes. Now, the relaxation is certainly dominated by modulation of the quadrupolar interaction, which is intramolecular and site specific. In addition, it is possible to obtain the spectral densities, $J_1(\omega_0)$ and $J_2(2\omega_0)$, rather than their sum R_1 (see *Deuteron Relaxation Rates in Liquid Crystalline Samples: Experimental Methods*). This is a particular advantage since director fluctuations are predicted to contribute only to $J_1(\omega_0)$, and thus if this mechanism dominates then this spectral density should depend on $\omega_0^{-1/2}$, whilst $J_2(2\omega_0)$ will be frequency independent. This is indeed what is observed⁷ for the deuterons in perdeuterated 1,4-diethynylbenzene dissolved in a nematic solvent, even though the measurements were made in the megahertz range, which is well above the range where director fluctuations are thought to produce a large contribution to the relaxation rates of nuclei in the solvent, mesogenic molecules.

This apparent paradox is resolved by theories of the magnitude of R_1^{DF} , which allow for a contribution which depends on both whole-molecule rotational motion and director motion. Thus, in a model introduced by Freed,⁸

$$R_1^{\text{DF}} = A[U(\omega_c/\omega_0)\omega_0^{-1/2} - (\sqrt{8/\pi})\tau_{\parallel}\omega_c^{1/2}] \quad (31)$$

The molecules are assumed to be rigid and cylindrically symmetric, and $\tau_{\parallel}$ is a correlation time for rotation about an axis perpendicular to the cylinder axis. The value of A is dependent on the orientational order of the molecules and also on the viscosity and elastic constants of the bulk liquid crystal. The frequency ω_c is an upper limit to the director modes, and we shall return to a discussion of the value associated with it of λ_c , the shortest wavelength of the modes; $U(\omega_c/\omega_0)$ is a function whose form can be found in the original paper,⁸ but which need not concern us now. First, note that the two terms in equation (31) are of opposite sign, and it is this which provides an explanation of the observation that director fluctuations can play a negligible role for the nuclear relaxation of nuclei in the solvent molecules, whilst dominating for nuclei in small solutes. This is because $\tau_{\parallel}$ is very short for small

molecules and the cross term is negligible, whilst for the mesogens themselves, this correlation time is orders of magnitude larger and hence the cross term is significant. Indeed, it is possible, in theory, for the two terms in equation (31) to cancel, or for the result to be negative! In consequence, relaxation of nuclei in molecules in liquid crystalline phases can be dominated by either director fluctuations, or molecular motions, or for director fluctuations to produce an attenuating effect on R_1 .

Although Freed's theory provides an explanation of how director fluctuations can have a quite different effect on the relaxation rates of nuclei in solute and solvent molecules, it does so by extrapolating beyond the range of one of its basic assumptions, which is that director fluctuations are much slower than molecular rotations. Gertner and Lindenberg,⁹ however, have shown that this difficulty is circumvented by using a generalized Langevin approach to solve the appropriate equations of motion. In this theory it is not necessary to assume that the motion of the molecules is much faster than that of the director, and they obtain essentially the same result as Freed.

One difficulty does remain. This concerns the values which are necessary for ω_c , which correspond to values of λ_c , since to fit the observed relaxation rates, these have to be of the order of a molecular length. This seems inconsistent with the continuum model used for the director modes, that is, it is assumed that the motion involves a sufficiently large number of molecules that the motion of individual molecules can be subsumed into a continuum. A short value for λ_c also implies that the order parameters obtained from NMR measurements, which are relative to B_0 as a fixed direction, will be significantly smaller than values relative to an instantaneous director. If this is correct then there are important consequences for the interpretations of the orientational order parameters which are derived from dipolar or quadrupolar splittings.

6.1.4 Exchange Processes and Paramagnetic Impurities

The effect of exchange processes on spectra are discussed by Luz and Poupo (see *Dynamic NMR in Liquid Crystalline Solvents*), and these processes can also contribute to relaxation rates.

Dipolar coupling to quadrupolar nuclei are also affected by the rate of spin–lattice relaxation of that nucleus.¹⁰ The effect is identical to that in isotropic samples, so that fast relaxation of the quadrupolar nucleus can lead to line broadening or to complete decoupling of the dipolar interaction to a spin- $\frac{1}{2}$ nucleus, such as a proton or carbon-13 (see Section 8.1).

Paramagnetic impurities, such as oxygen, can increase relaxation rates significantly for protons, and perhaps carbon-13, and should be removed from the sample. They have a negligible effect for deuterium in most samples, partly because of the lower gyromagnetic ratio, but also because of the shorter relaxation times of this nucleus produced by the quadrupolar mechanism.

7 PROTON NMR OF LIQUID CRYSTALLINE SAMPLES

7.1 The Spectra of Mesogenic Molecules

The spectra are dominated by interproton dipolar couplings, which for most mesogens leads to very broad, unresolved spec-

Figure 4 A 200 MHz spectrum of the protons in 4-methoxy-4'-cyanobiphenyl dissolved in the nematic phase of ZLI 1132

tra. An exception is provided by 4-methoxy-4'-cyanobiphenyl (IOCB), which is the simplest mesogen, and which does yield a well-resolved spectrum when in a supercooled nematic phase. This spectrum has proved impossible to analyze so far, but the better resolved spectrum (shown in Figure 4) of this mesogen dissolved in a nematic mixture (ZLI 1132) has been analyzed to yield 17 dipolar couplings.¹¹

The analysis of such a complex spectrum is a formidable task, which was accomplished only by first analyzing the simpler, deuterium decoupled spectra from partially deuterated samples. This is a general method of simplifying complex proton spectra, which has been applied to the proton spectra of other mesogens (see *Liquid Crystalline Samples: Spectral Analysis*).

The dipolar couplings obtained from the analysis of the proton spectrum of IOCB were interpreted in terms of the minimum energy conformations of the molecule, the nature of the potentials governing internal bond rotations, and the orientational order. IOCB, like all mesogens, is a flexible molecule, and an account of how to analyze such data is given elsewhere (see *Liquid Crystalline Samples: Structure of Nonrigid Molecules*).

7.2 Proton Spectra of Solute Molecules

The proton spectra of the solute is superimposed on that of the solvent, but a separation of the two can usually be made based on the different linewidths. Thus, either convolution difference or Gaussian multiplication techniques can provide the spectrum of the solute alone. Figure 5 shows the proton spectrum of phenyl benzoate dissolved in a nematic solvent ZLI 1132, which is a mixture of three mesogenic molecules, before and after the application of Gaussian deconvolution and a baseline correction.

The maximum number of interacting protons in a molecule from which a resolved spectrum can be obtained is about 12, and this also represents the current limit on analysis. Of course, just as with mesogens, the spectra can be simplified by deuteration combined with decoupling, or multiple quantum spectroscopy, and hence more complex molecules can be studied.

Figure 5 A 200 MHz spectra of the protons in phenyl benzoate dissolved in the nematic solvent ZLI 1132 before (top) and after (bottom) Gaussian deconvolution and baseline correction

7.3 Proton Relaxation Rates

Proton relaxation rates are similar in magnitude to those in isotropic samples of similar viscosity. As noted in Section 5.1.3, the frequency dependence of R_1 for protons in mesogens, as obtained by field cycling, have led to an understanding of the relative importance of director fluctuations as a relaxation mechanism. It is not possible, however, to obtain useful information on the dynamics of the individual molecules in liquid crystalline phases from proton relaxation, primarily because of the unresolved nature of the spectra. There would indeed be a wealth of information available from relaxation experiments on the resolved spectra that can now be easily obtained from deuterium decoupling partially deuterated samples, but no such studies have been attempted.

8 CARBON-13 NMR

8.1 Proton Decoupled Carbon-13 Spectra of Mesogenic Molecules

These are the simplest carbon-13 spectra, and have a limited information content, but they have the advantage of being very easily analyzed. The more informative local field spectra obtained with near magic angle spinning are discussed by Fung (see *Liquid Crystalline Samples: Carbon-13 NMR*).

Decoupling the proton–carbon dipolar interactions requires more power than for isotropic samples. This can lead to a rise

in temperature which is sufficient to broaden the lines, and so care must be taken in the design of the experiment. The simplest decoupling method consists in applying the proton decoupling field only when acquiring data, and in limiting this period to avoid sample heating. A delay between acquisition is introduced of about 3 s to allow the sample to cool. More efficient decoupling methods have been proposed.¹²

A case study is presented here of 4-*n*-pentyl-4'-cyanobiphenyl (5CB), which forms a nematic phase, with the aim of showing what information can be obtained from such carbon-13 spectra. Figure 6 shows proton-decoupled carbon-13 spectra of 5CB. Spectrum (a) is for the sample in the isotropic phase, and here the linewidths are limited by the probe being used (a high-power, double-tuned solenoid designed for cross-polarization studies on solid samples). Spectrum (b) is for the sample in the nematic phase, and now the lines are considerably broader, which is partly because R_2 is larger in the oriented phase, but is also probably a result of incomplete decoupling plus sample heating. Note that the presence of ^{14}N in the molecules does not lead to either resolved couplings or to line broadening.

Spectrum (b) demonstrates the basic information content of proton decoupled carbon-13 spectra. Firstly, the lines are relatively sharp, showing that the directors are aligned uniformly, in this case along B_0 since the sample has a positive $\Delta\chi$. Secondly, the line positions change between the two phases. The aliphatic carbon resonances shift upfield by relatively small amounts, and come closer together, whereas the aromatic carbon resonances are all shifted downfield, and are more dispersed. Note the very large upfield shift of the nitrile carbon, which is hidden beneath the aliphatic peaks.

The shift in the line positions $\Delta\delta_i$ from isotropic to liquid crystalline phase is determined by the anisotropy in the shielding tensor $\sigma_{zz}^{\text{aniso}}$ [see equation (19)] which, if intermolecular contributions can be neglected (see *Anisotropy of Shielding and Coupling in Liquid Crystalline Solutions*), is related to components in a molecular frame $\sigma_{\alpha\beta i}$, and order parameters $S_{\alpha\beta}$, [see equation (20)]. The order parameters are those for axes fixed in the fragment containing nucleus i , and for a flexible molecule such as 5CB they are not order parameters for the whole molecule. To be specific, fixing axes in fragment 2, then these are principal axes for the *local* order matrix of ring 1, and

$$\Delta\delta_i = \frac{2}{3}S_{aa}\{\sigma_{aai} - \frac{1}{2}(\sigma_{bbi} + \sigma_{c ci})\} + \frac{1}{3}(S_{bb} - S_{cc})(\sigma_{bbi} - \sigma_{c ci}) \quad (32)$$

If the shielding tensor components are known, then the *local* order parameters can be obtained from the measured values of $\Delta\delta_i$. Conversely, if the local order parameters can be obtained from dipolar couplings or quadrupolar splittings, as indeed they have been¹³ for 5CB, then the shielding components can be obtained. It should be noted, however, that it is

Figure 6 50 MHz proton-decoupled carbon-13 spectra of 4-*n*-pentyl-4'-cyanobiphenyl (5CB): (a) isotropic, (b) nematic, and (c) [¹⁵N]5CB in the nematic phase

very difficult to measure $S_{bb} - S_{cc}$ with high precision and this, together with its small values (approximately $S_{aa}/10$), makes it impossible to separate the two terms in equation (32) experimentally. This situation occurs for most mesogenic compounds, and so it is better to approximate equation (32) as

$$\Delta\delta_i = \frac{2}{3}S_{aa}\{\sigma_{aai} - \frac{1}{2}(\sigma_{bbi} + \sigma_{cci})\} \quad (33)$$

and to recognize that there will be a small systematic error in using this equation to obtain either S_{aa} or the molecule anisotropy $\Delta\sigma_i = \sigma_{aai} - \frac{1}{2}(\sigma_{bbi} + \sigma_{cci})$.

The values of $\Delta\delta_i$ for carbon-13 nuclei in the second ring can be used in a similar way, again to obtain S_{aa} or $\Delta\sigma_i$. The shifts for the aliphatic carbon atoms can also, in principle,

be used to obtain local order parameters, or shielding tensor components. For the methyl group the rapid rotation about the C–CH₃ bond leads to

$$\Delta\delta_{CH_3} = \frac{2}{3}S_{CC}(\sigma_{\parallel}^{CC} - \sigma_{\perp}^{CC}) = \frac{2}{3}S_{CC}\Delta\sigma^{Me} \quad (34)$$

where S_{CC} is the *local* order parameter for the C–C bond direction, and $\sigma_{\parallel}^{CC}$ and $\sigma_{\perp}^{CC}$ are components of the shielding tensors for the methyl carbon atoms parallel and perpendicular to the C–C bond direction, respectively.

The methylene carbon atoms are part of the rigid fragment 3, which has no symmetry, and therefore the location of the principal axes for the *local* order matrix is unknown. This means that the values of $\Delta\delta_i$ for methylene carbon atoms cannot be used to obtain either components of the shielding tensor elements, or the local order parameters.

Spectrum (c) in Figure 6 is of 5CB labeled with ¹⁵N instead of ¹⁴N, and is an example of the value of having a third, active nucleus in the molecule.¹⁴ The carbon atoms close to the ¹⁵N show doublets from ¹⁵N–¹³C dipolar plus spin–spin coupling: the splittings are $\tilde{J}_{zzij} + 2\tilde{D}_{zzij}$, and may be used¹⁵ for this molecule to obtain local order parameters S_{aa} and $S_{bb} - S_{cc}$.

8.2 Carbon-13 Relaxation Rates

The relaxation rates R_{1i} for each resolved resonance can be obtained by the inversion–recovery experiment, and there is a clear advantage in using ¹³C rather than ¹H relaxation rates to investigate the dynamics of mesogenic molecules. There have, however, been only a relatively small number of studies of ¹³C relaxation in thermotropic liquid crystalline phases,^{16–20} in part because of the difficulties in ensuring complete proton decoupling, but also because of the uncertainty in the mechanisms contributing to the values of R_{1C} . There have been more studies on amphiphilic systems,^{21–23} the work prior to 1987 being summarized by Chachaty.²³

The dominant mechanism for ¹³C relaxation at high fields (such that director fluctuations can be ignored) is usually modulation of the ¹³C–¹H dipolar interactions by whole-molecule and internal rotational motion. There may also be a contribution from modulation of the shielding anisotropy, which will increase in importance with B_0 .² Early studies by Levine et al.²¹ established the importance of the bond rotational motion in alkyl chains in amphiphilic molecules, where R_{1i} decreases uniformly from carbon atoms close to the headgroup to the methyl carbon atom. A similar decrease is expected for any chain carbon atoms which are attached at one end. This, incidentally, provides a method for assigning these resonances.

9 DEUTERIUM NMR

Most NMR studies on liquid crystals are of deuterium. This nucleus has advantages for studies of orientational order,

Figure 7 Simulated spectra of a pair of deuterons related by reflection symmetry (as in a CD_2 group) with $\Delta\nu/D$ (a) positive, and (b) negative

phase type, and molecular dynamics, and these outweigh the disadvantage that compounds have to be enriched with deuterium to yield observable resonances.

9.1 Deuterium Spectra

9.1.1 Deuterium Spectra of Aligned Samples

Each chemically equivalent group of deuterons gives a doublet (separation $\Delta\nu_i$) from the quadrupolar interaction, which may be split further by $^2\text{H}-^2\text{H}$ or $^2\text{H}-\text{X}$ dipolar couplings. The dipolar couplings are usually considerably smaller than the quadrupolar splitting $\Delta\nu_i$, so that spectra are often observed as superpositions of simple doublets. It should be noted that the splitting patterns produced by dipolar coupling D_i , between deuterons within the chemically equivalent groups can be very useful, either as sources of extra order parameters, or in giving the relative signs of $\Delta\nu_i$ and D_i . For example, Figure 7 shows the theoretical spectra for a group containing two equivalent deuterons, as in a CD_2 group, for a negative and positive value of the ratio $\Delta\nu_i/D_i$.

The spectra of CD_3 groups also depend on the sign of the ratio $\Delta\nu_i/D_i$, but now this is dependent only on the geometry of this group and not on the orientational order. The ratio is usually found¹³ to lie in the range -215 ± 15 .

Figure 8 shows the spectrum from the deuterons in $5\text{CB}-d_{15}$ in the nematic phase, and the dipolar coupling structure can be clearly seen on some of the peaks. The assignment of the lines poses a problem similar to that of $^{13}\text{C}-\{^1\text{H}\}$ spectra, but one which cannot be solved by the same methods used for isotropic samples. The only certain method of assignment of peaks of equal intensity, such as those in CD_2 groups along an

Figure 8 A 30.7 MHz spectrum of the deuterons in $5\text{CB}-d_{15}$ in the nematic phase. The peaks labeled 1–5 are from deuterons in the alkyl chain, 5 being the methyl group, and those labeled R1–4 are from deuterons in the alkyl substituted ring

alkyl chain, is to synthesize specifically labeled compounds. If this is not an option, the peaks from CD_2 groups in an alkyl chain can be assigned from their R_1 values, which have been found experimentally, and predicted theoretically, to decrease uniformly along the chain towards the methyl group.²⁴

9.1.2 Deuterium Spectra of Unaligned Samples

A sample in which all orientations of the director with respect to $\mathbf{B}_0$ are equally probable gives the same lineshape as that for a polycrystalline solid sample (see Figure 2), the difference between the two cases being that the liquid crystalline powder spectrum is reduced in width. The separations of the outer edges and inner horns for a uniaxial phase are

$$\Delta\nu_{\text{outer}} = \frac{3}{2}q_{aa}\{S_{aa} + \eta(S_{bb} - S_{cc})\} \quad (35)$$

$$\Delta\nu_{\text{inner}} = -\frac{1}{2}\Delta\nu_{\text{outer}} \quad (36)$$

Here a , b , and c , are axes fixed in the rigid fragment containing the deuteron, and they are principal axes either for $\mathbf{q}_i$ or $\mathbf{S}^i$. Choosing them to be principal axes for $\mathbf{q}_i$, then they are such that $q_{aa} > q_{bb} > q_{cc}$, so that

$$\eta = (q_{bb} - q_{cc})/q_{aa} \quad (37)$$

is positive.

For deuterons in C–D bonds, a lies approximately along the bond direction, and η is usually <0.1 . The effect of η on a powder spectrum is to introduce shoulders on the inner horns.

Figure 9 shows an example of the ^2H spectrum of potassium stearate- d_{35} in an unaligned sample of a lamellar

Figure 9 Deuterium spectrum of potassium stearate- d_{35} dissolved in the lamellar phase of a potassium oleate-water system²⁵

phase. All 35 protons are replaced by deuterons, giving 17 overlapping powder patterns. Extracting order parameters from such a spectrum requires identifying the inner horns from each powder pattern, and this was indeed achieved for this spectrum.²⁵ An elegant method of deconvoluting such spectra into the separate powder patterns has been proposed by Bloom et al.,²⁶ and is referred to as ‘de-Paking’.

Deuterium powder patterns from liquid crystalline samples are particularly useful for detecting the biaxiality of the phase. This is discussed in detail by Doane²⁷ for biaxial lyotropics, smectics, cholesterics (chiral nematics), and blue phases. Luz et al.²⁸ discuss the deuterium spectra of discotic phases, including biaxial phases.

9.2 Relaxation Rates of Deuterons

Deuterium is, without question, the nucleus of choice for studying relaxation, and hence the dynamics of molecules in liquid crystalline phases. A wealth of experimental data may be obtained, particularly for aligned samples. In this case, the spectral densities $J_1(\omega_0)$ and $J_2(2\omega_0)$ are easily obtained for each group of deuterons, giving resolved quadrupolar splittings (see *Deuteron Relaxation Rates in Liquid Crystalline Samples: Experimental Methods*). Even more spectral densities can be obtained if the sample can be studied with different orientations Ω of the magnetic field with respect to the director. Thus,

$$J_n(n\omega_0, \Omega) = \sum_p (D_{p,n}^2(\Omega))^2 J_p(p\omega_0) \quad (38)$$

For a uniaxial phase it is possible, in principle, to obtain $J_1(0)$, $J_1(\omega_0)$, $J_1(2\omega_0)$, $J_2(0)$, $J_2(\omega_0)$ and $J_2(2\omega_0)$ from the angular dependences of $J_1(\omega_0)$ and $J_2(2\omega_0)$.

Deuterium relaxation rates are also dominated by one mechanism, i.e. the modulation of the quadrupolar interaction. The important sources of this modulation are whole molecule rotations, and for flexible molecules, internal bond rotations. Director fluctuations are probably important only at frequencies well below those used in NMR spectrometers (see *Liquid Crystalline Samples: Deuterium NMR*).

1 INTRODUCTION

NMR spectra of oriented molecules are extremely rich in their information content, but they become rapidly more complex as the number of interacting nuclei increases. The spectra are, in general, invariably 'strongly' coupled. This is particularly the case for spectra in thermotropic liquid crystals, unless heteronuclei are involved. On the other hand, in heteronuclear cases, it is not possible to determine the direct dipolar and the indirect spin-spin couplings individually from such spectra. Such difficulties lead to major obstacles in the routine applications of this technique to complex and heteronuclear systems. In order to enhance the scope of the technique, these problems have attracted the attention of several workers ever since the potential of the technique in the study of molecular structure and function was realized. The employment of specifically deuterated compounds with deuterium decoupling;^{1,2} deuteron NMR spectroscopy in perdeuterated samples;³ multiple quantum spectroscopy;⁴ two-dimensional NMR⁵ including the state correlated technique;⁶ solvents with low order parameters;⁷ electric⁸ and magnetic⁹ fields for orienting the molecules; and mixed liquid crystals of opposite diamagnetic anisotropy, are some of the steps in this direction.^{10,11} This article describes the developments, progress, scope, limitations and novel applications of the NMR spectroscopy of systems oriented in mixed liquid crystals of opposite diamagnetic anisotropies ($\Delta\chi$).

2 EXPERIMENTAL TECHNIQUES

It has been observed^{10,11} that the direct dipole-dipole coupling constants (D_{ij}) between two interacting nuclei i and j of the solute molecules dissolved in a mixture of two nematic liquid crystals with opposite $\Delta\chi$ values vary gradually as the relative concentrations of the two solvents are changed. When a critical point is reached, the D_{ij} values change abruptly either to twice or to half the particular value, with opposite sign, depending upon the direction of

Figure 1 Dipolar couplings between methyl protons, $D(\text{H,H})$, in acetonitrile ($\circ$) and those between *ortho* protons (D_{ortho}) in benzene (∇) as a function of the relative concentrations of EBBA and ZLI 1167 at 270 MHz. Temperature 22°C; solute concentration 3.3 wt %

approach of the critical concentration. Beyond this point, they revert to a gradual variation. A typical plot of the proton-proton dipolar coupling [$D(\text{H,H})$] in acetonitrile and the dipolar coupling between the *ortho* protons (D_{ortho}) of benzene as a function of the concentration of *N*-(*p*'-ethoxybenzylidene)-*p*-*n*-butylaniline (EBBA) ($\Delta\chi > 0$) and ZLI 1167 (Merck; an eutectic mixture of three *p*-cyano-*p*'-alkylcyclohexylcyclohexanes with propyl, pentyl and heptyl as the alkyl groups) ($\Delta\chi < 0$) is shown in Figure 1.

Around the critical concentration the abrupt variation in the dipolar coupling can also be obtained by changing the temperature. In fact, at the critical concentration and temperature, the observed spectrum consists of a superposition of two spectra, the dipolar couplings of one spectrum being twice those of the other, and of the opposite sign. The two spectra correspond to two different orientations of the two types of solvent. The orientation corresponding to that of the liquid crystal with $\Delta\chi > 0$ is such that the liquid crystal director is oriented parallel to the direction of the magnetic field, and in the solvent with $\Delta\chi < 0$ the director is oriented perpendicular to the magnetic field. The proton NMR spectra of acetonitrile above, below and at the critical temperature and for a given concentration are shown in Figure 2. At 21 °C two spectra are observed simultaneously.

The results can be understood in terms of the switching of the liquid crystal director by 90° at the critical point. The spectra, at temperatures and concentrations just above and just below the critical levels, result from the orientations corresponding to the solvents of positive and negative diamagnetic anisotropies. At the critical concentration and temperature where the orienting influences of both solvents are comparable, the spectra from both orientations coexist. This phenomenon has led to some new applications, which are described below.

Figure 2 Proton NMR spectra of acetonitrile oriented in the nematic phase of a mixture of EBBA and ZLI 1167. Solute concentration: 3.3 wt % in 77.57% ZLI 1167 and 22.43% EBBA at different temperatures. The lines marked with an asterisk arise from traces of water in the solution. (a) ‘Parallel’, (b) ‘coexisting’, and (c) ‘perpendicular’ orientations

3 THEORETICAL INTERPRETATION

Mean field¹² and Landau-type theories^{13–16} have been used to interpret the above-described behavior of the dipolar couplings. The theories provide good agreement for the dipolar couplings in various systems and explain the switching transition at a critical concentration and temperature and the coexistence of the two orientations.

The free energy function $F(S_{\parallel}, S_{\perp}, T)$ of the system has been expanded in terms of powers of the order parameters $S_{\parallel}$ and $S_{\perp}$:

$$F = F_0 - a(1 - X_1)S_{\parallel}^2 + bS_{\parallel}^4 - A(1 - X_2)S_{\perp}^2 + BS_{\perp}^4 + C_1\langle S_{\perp}^2 \rangle S_{\parallel}^2 + C_2\langle S_{\parallel}^2 \rangle S_{\perp}^2 \quad (1)$$

where X_p defines the concentration ratio of component p and is given by $X_p = \alpha_p/\alpha_{cp}$ such that α_p denotes the concentration of p and α_{cp} defines its value at the critical point. Minimization of the free energy function with respect to $S_{\parallel}$ or $S_{\perp}$ gives the following condition for the parallel- and perpendicular-orientation dominated regions, respectively:

$$S_{\parallel}^0 = - \left[\frac{a(1 - X_1) - C_1\langle S_{\perp}^2 \rangle}{2b} \right]^{\frac{1}{2}} \quad (2)$$

$$S_{\perp}^0 = - \left[\frac{A(1 - X_2) - C_2\langle S_{\parallel}^2 \rangle}{2B} \right]^{\frac{1}{2}} \quad (3)$$

It has been shown that the order parameter in the parallel-orientation dominated region is

$$\frac{\frac{1}{2} - 6(b/k_B T)(S_{\parallel}^0)^2 \left[\frac{9}{28} + \left(\frac{S_{\parallel}^0 + \frac{1}{2}}{3} \right)^2 - \frac{3}{5} \left(S_{\parallel}^0 + \frac{1}{2} \right) \right]}{1 - 4(b/k_B T)(S_{\parallel}^0)^2 \left[\frac{9}{20} + \left(S_{\parallel}^0 + \frac{1}{2} \right)^2 - \left(S_{\parallel}^0 + \frac{1}{2} \right) \right]} - \frac{1}{2} \quad (4)$$

where k_B is the Boltzmann constant and the value of $C_1 \cdot \langle S_{\perp}^2 \rangle$ has been chosen as

$$C_1\langle S_{\perp}^2 \rangle = C_1 X_1 h(1 - X_1) \quad (5)$$

where $h(1 - X_1)$ is a step function and is zero for a negative value of the argument and unity for positive values. An expression similar to equation (4) has been obtained for the perpendicular-orientation dominated regions by replacing b and $S_{\parallel}^0$ by B and $S_{\perp}^0$, respectively. The value of $C_2\langle S_{\parallel}^2 \rangle$ has been chosen as in equation (5) as follows:

$$C_2\langle S_{\parallel}^2 \rangle = C_2 X_2 h(1 - X_2) \quad (6)$$

It should be noted that, at the point of transition, the order parameter given by equation (4) and the corresponding equation for the perpendicular-orientation dominated region vanish. This implies the coexistence of the two types of orientation.

In order to compare the theoretical and the experimental findings, dipolar couplings have been used to obtain the order parameters. The order parameters were then normalized by dividing them by the largest value in each region. The coefficients to be determined are a , b , A , B , C_1 , and C_2 ; these were estimated according to their agreement with the normalized data. The graphs obtained using these parameters derived via theoretical considerations are given in Figure 3 together with experimental data points. The agreement is very good. It shows the correct trend and switching of the order parameters near the critical concentration. It is also worth emphasizing that the parameters $(a/2b)$, $(b/k_B T)$, $(C_1/2b)$, $(A/2B)$, $(B/k_B T)$ and $(C_2/2B)$ were found to be almost

Figure 3 Calculated and experimental plots of the order parameters as a function of the relative concentrations of the liquid crystal solvents. α_E and α_Z refer to the relative concentrations of the solvents: benzene in ZLI 1167 + EBBA (●, experimental points; —, theoretical curve); acetonitrile in ZLI 1167 + EBBA (○, experimental points; , theoretical curve); acetonitrile in ZLI 1167 + S-1114 (×, experimental points; ----, theoretical curve)

independent of the particular solvent or the solute molecules. Similar results are shown for the switching transition observed (near the critical concentration) as a function of temperature.

Attempts have also been made to determine experimentally the exact origin of these results. The appearance of a 'powder pattern' at the critical point has been demonstrated¹⁷ from the spectrum of 1,3,5-trichlorobenzene in a critical mixture of two nematic liquid crystals of opposite diamagnetic anisotropies. Other comments on the experimental verification of such effects have also been made.¹⁶ In spite of these difficulties, the experiments lead to several novel applications of NMR spectroscopy of oriented molecules; these are described in the following section.

4 APPLICATIONS

The study of NMR spectra at the 'coexistence point' has led to the following novel applications:

1. separate determination of the indirect spin–spin (J_{AX}) and the direct dipolar couplings (D_{AX}) between heteronuclei;
2. determination of the chemical shift anisotropy ($\Delta\sigma$);
3. determination of the diamagnetic susceptibility anisotropy ($\Delta\chi$) of liquid crystals;
4. precise determination of spectral parameters;
5. assignments of spectral lines in the ^{13}C spectra of liquid crystals;
6. study of the dynamics of the liquid crystal director;
7. study of the orientation and distortions in tetrahedral and spherical molecules.

4.1 Determination of Indirect Couplings Between Heteronuclei (J_{AX})

When A and X are heteronuclei, NMR spectra of oriented molecules provide the sum ($J_{AX} + 2D_{AX}$) instead of the individual coupling constants. Therefore, to obtain correct values of D_{AX} , the values of J_{AX} must be known. As J_{AX} may be solvent and temperature dependent, especially when heavier nuclei are involved, it is worth obtaining values in the nematic phase itself without changing the experimental conditions. These values may be obtained from the spectra at the 'coexistence point'. The parameters ($J_{AX} + 2D_{AX}$) and ($J_{AX} - D_{AX}$) can thus be obtained, where D_{AX} is the dipolar coupling for the orientation corresponding to that for the parallel orientation. The values of J_{AX} and D_{AX} can then be determined.

The first demonstration of this particular application was for acetonitrile. The values of the various heteronuclear indirect spin–spin couplings thus obtained were found to agree well with those reported from studies in the isotropic media.¹¹

No values for the indirect selenium–proton couplings in phenylselenyl halides (chloride and bromide) have been reported. The proton spectra of the isotropic media contain ^{77}Se satellites. These small satellite lines are masked by the huge proton lines arising from species having a much greater abundance of the nonmagnetic selenium isotopes, and thus the selenium–proton couplings cannot be easily determined. However, the values have been determined from the spectra of the phenylselenyl halides in a mixture of ZLI 1167 and

Figure 4 Proton NMR spectra of a 7wt% solution of CH_3PCl_2 oriented in 1:1 wt % solution of S-1114 and ZLI 1167 at 270 MHz

Merck Phase IV at the 'coexistence point'.^{18,19} In addition to determining the vibrationally corrected r_α structure, the chemical shift anisotropy, and the sign and magnitude of the indirect P–H coupling in methyldichlorophosphine, the authors interpreted the abnormal orientation of the molecule in terms of the formation of a solvent–solute complex.²⁰ Typical spectra are shown in Figure 4.

4.2 Determination of Chemical Shift Anisotropy $\Delta\sigma$

Various methods are available for determining $\Delta\sigma$ from NMR spectra of oriented molecules. Most of these methods suffer from drawbacks arising from changes in the experimental conditions, such as temperature and concentration, and the use of external or internal references. All these factors lead to uncertainties in the values of $\Delta\sigma$ determined. An interesting comparison has been made of the values of the chemical shift anisotropies determined using the various methods.²¹ It is observed that the uncertainties, particularly those in the proton chemical shift anisotropies, may sometimes be larger than the magnitudes of $\Delta\sigma$. However, when the spectra recorded at the 'coexistence point' are used, $\Delta\sigma$ can be obtained without changing the experimental conditions and also in the absence of a reference compound. This approach provides very consistent results for $\Delta\sigma$ in various solvents, virtually independent of the solvent effects.

The chemical shift in the nematic phase (σ_a) for a molecule with a three-fold or higher axis of symmetry is given by

$$\sigma_a = \sigma_i + \frac{2}{3} \Delta\sigma \cdot S_{C_3} \quad (7)$$

where σ_i is the isotropic chemical shift and S_{C_3} is the order parameter of the C_3 axis of symmetry.

The use of the condition in which the order parameters for the coexistence of the two orientations are related by $(S_{C_3})_{\parallel} = -2(S_{C_3})_{\perp}$, leads to

$$\Delta\delta = \frac{(\sigma_a)_{\parallel} - (\sigma_a)_{\perp}}{(S_{C_3})_{\parallel}} \quad (8)$$

Figure 5 Proton NMR spectra of 3 wt % benzene oriented in a 0.3:1.0 (by weight) mixture of EBBA + ZLI 1167 at 270 MHz. The lines marked with an asterisk arise from traces of water in the solution

where $(\sigma_a)_\parallel$ and $(\sigma_a)_\perp$ are the chemical shifts for the conditions $\Delta\chi > 0$ and $\Delta\chi < 0$, respectively.

The first such measurement of $\Delta\sigma$ (for acetonitrile protons) gave a value of -2.01 ± 0.01 ppm.¹¹ Subsequently, the method has been used to measure $\Delta\sigma$ for acetonitrile in a large number of mixtures, and has given very consistent results.²¹ This method of determining $\Delta\sigma$ has been named the ‘NEMIX method’.²¹ Measurements of the proton chemical shift anisotropies of systems such as benzene and 1,3,5-trichloro-, bromo-, and nitrobenzenes using this technique have also been reported.²² Typical spectra for benzene are shown in Figure 5. For benzene, a value of -1.49 ± 0.01 ppm was obtained, which is smaller than the values obtained using other techniques. This might be due to different local effects of the various methods and to additional unknown factors influencing the various techniques. Using this technique, the ^{13}C chemical shift anisotropy for the methyl carbon in acetonitrile was found to be 16.6 ± 0.4 ppm. The corresponding values for 1,3,5-tribromobenzene are -260 and -275 ppm for the carbon atoms attached to proton and bromine, respectively.

It should be emphasized that different local effects may play an important role even in this method. This has been clearly demonstrated by measuring the proton chemical shift anisotropy of tetramethylsilane (TMS) using spectra recorded at the ‘coexistence point’ in EBBA + ZLI 1167. It was found that the TMS spectra corresponding to the parallel and perpendicular orientations do not have signals at the same frequency, but are chemically shifted by 0.421 ppm.^{23,24} This results in an absurd value of $\Delta\sigma$. An NMR study of methanol recorded at the ‘coexistence point’ provided a value of -104.3 ppm for the chemical shift anisotropy of the methyl protons.²³ This value of $\Delta\sigma$ is abnormally large and unrealistic. Such behavior can be understood in terms of a multiple site theory analogous to that reported for dipolar and quadrupolar couplings, and solvent effects.

4.3 Determination of Diamagnetic Susceptibility Anisotropy ($\Delta\chi$)

At the critical point, the macroscopic diamagnetic anisotropy of the system vanishes. This implies that

$$p(\Delta\chi)_\parallel + (1 - p)(\Delta\chi)_\perp = 0 \quad (9)$$

where p is the mole fraction of the solvent with $\Delta\chi > 0$. Both $(\Delta\chi)_\parallel$ and $(\Delta\chi)_\perp$, which are the diamagnetic anisotropies of components with $\Delta\chi > 0$ and $\Delta\chi < 0$, respectively, are dependent on the degree of order of the liquid crystal (S_{LC}) as $\Delta\chi = S_{\text{LC}}\Delta\chi_a$, where $\Delta\chi_a$ is the molar susceptibility anisotropy.

The relative diamagnetic anisotropies of the solvents can be derived using a solute molecule as a probe. This method has been used to obtain relative $\Delta\chi$ values with acetonitrile as the probe molecule.²⁵ Knowledge of the diamagnetic anisotropy of one component gives the value of the other. A value of $\Delta\chi$ at 295 K for ZLI 1167 has thus been obtained as $-4.5 \pm 0.2 \times 10^{-8}$ cgs cm⁻³. This value has been used to determine $\Delta\chi$ for a number of other liquid crystals with $\Delta\chi > 0$.

4.4 Precise Determination of Spectral Parameters

In a spin system with a relatively small number of independent transitions, the spectral parameters determined may contain large uncertainties. Such a situation has been encountered²⁶ in 2,6-dichlorophenol, the proton spectrum for which is of the AB₂ type (due to rapid exchange of OH protons in a mixture of EBBA and ZLI 1167). Each spectrum contains nine lines with fairly large linewidths (≈ 20 Hz). When all the spectral parameters [(i.e. $\nu_A - \nu_B$, D_{AB} , D_{BB} , and J_{AB} (J_{BB} does not influence the spectrum))] were derived from each spectrum separately, the values determined, particularly those for J_{AB} , were not in agreement with each other or with the literature values for similar systems. However, when the two spectra recorded at the ‘coexistence point’ were investigated and the fact that the dipolar couplings in the two are not independent (related by a factor of -2) was taken into consideration, it was found that all the parameters could be obtained with reasonable accuracy. J_{AB} determined from the individual spectra were -7.3 and $+10.1$ Hz, but using the ‘coexisting phase’ spectrum a value of 8.3 Hz was obtained. A separate determination of the value in the isotropic phase also yielded a value of 8.3 Hz for J_{AB} .

4.5 Assignment of ^{13}C Spectral Lines in the ^{13}C Spectra of Liquid Crystals

Assignments of the resonances in the ^{13}C NMR spectra of isotropic systems can be made from off-resonance decoupled spectra and two-dimensional $^{13}\text{C}/^1\text{H}$ heteronuclear COSY experiments. However, it is not so easy to make these assignments of ^{13}C spectra in the nematic phase. The mixture of liquid crystals of opposite diamagnetic anisotropies provides a convenient technique for such a purpose, as described below.

The chemical shift in the nematic phase for a nucleus i in the parallel and perpendicular orientations [$(\sigma_a)_\parallel$ and $(\sigma_a)_\perp$ respectively], the isotropic chemical shift α_i , the order parameter S , and the chemical shift anisotropy $\Delta\sigma$, are related as follows:

$$(\sigma_a)_\parallel = \alpha_i + \frac{2}{3}\Delta\sigma \cdot S \quad (10)$$

$$(\sigma_a)_\perp = \alpha_i - \frac{1}{3}\Delta\sigma \cdot S \quad (11)$$

The equations imply that the order parameter in the perpendicular orientation is $-\frac{1}{2}S$ at the critical concentration

Figure 6 Proton decoupled ^{13}C NMR spectra of a 0.3:1.0 wt % mixture of MBBA and ZLI 1167 at 75.47 MHz. In the assignments of the peaks the primes denote the perpendicular orientation; unprimed numbers denote the parallel orientation

where both orientations coexist. The equations also suggest that the separation between the line for the isotropic phase and the line for the parallel orientation is twice, and with opposite sign, compared with that between the isotropic phase and the perpendicular orientation. Thus the line pairs in the parallel and perpendicular orientations for the same nucleus can be assigned using the line positions in the spectra of isotropic media. This leads to unambiguous assignment of spectral lines in ^{13}C spectra. The technique has been applied²⁷ to liquid crystals such as *N*-(*p*'-methoxybenzylidene)-*p*-*n*-butylaniline (MBBA) and *trans*-4-pentyl-4-(4-cyanophenyl)cyclohexane (S-1114). Typical spectra for MBBA + ZLI 1167 are shown in Figure 6, and the chemical shift anisotropies of the individual carbon atoms were finally obtained.

4.6 Study of the Dynamics of the Liquid Crystal Director

Experiments have been carried out to study the dynamics of the liquid crystal director in 'near magic angle spinning' experiments on liquid crystal mixtures with near-zero macroscopic diamagnetic anisotropy.²⁸ The ^2H quadrupole splitting of deuteriochloroform dissolved in liquid crystals has been monitored. In systems with weakly positive diamagnetic susceptibility anisotropy, the director has been observed to switch from an orientation parallel to the spinning axis at low rotational speeds to one perpendicular to the spinning axis at high rotational speeds. This occurs when the angle θ which the axis of rotation makes with the magnetic field is smaller than the magic angle θ_m . For systems with small negative $\Delta\chi$, a similar director behavior has been observed for $\theta > \theta_m$.

Figure 7 ^{13}C NMR spectra of 0.2 wt % of fullerene (C_{60}) containing 4.2 wt % of TMS in a 1:1 mixture of S-1114 and ZLI 1167 at 332.4 K. The coexistence of the two spectra is evident in the case of tetramethylsilane ($\circ$). The C_{60} line is marked by asterisks

4.7 Orientation and Distortions of Tetrahedral and Spherical Molecules

Studies of this type have attracted the attention of several workers^{24,29–32} ever since the observation in 1966 of the splittings in the proton NMR spectra of oriented tetramethylsilane.³³ The splittings have been attributed to the small anisotropic pressures of the anisotropic media, which result in minor distortions of the molecules from perfect symmetry. A distortion of about 0.1° in the H–C–H or H–C–Si bond angles from the tetrahedral value in tetramethylsilane has thus been estimated. Subsequently, several theoretical and experimental reports have emerged in which attempts have been made to understand the behavior. Mixed liquid crystals containing opposite diamagnetic anisotropies have also been used in trying to understand such effects. In fact, the critical mixture proposed and used by Jokisaari et al. is the one in which the splittings in the proton spectrum of methane are minimal.²⁹ An experiment set up to study the extent of the distortion, (if any) in fullerene (C_{60}) has been reported; mixtures of liquid crystals of opposite diamagnetic anisotropies were used. The experiments were performed in a solution of fullerene in the critical mixture of S-1114 and ZLI 1167 containing small quantities of TMS (Figure 7). At the critical point where the ^{13}C spectrum of tetramethylsilane shows two lines due to two different orientations, fullerene shows a single line. The results indicate that fullerene remains undistorted in the liquid crystalline media and its perfect spherical symmetry is retained.

It should be noted that information on a system like fullerene cannot be easily obtained in any other way, as fullerene shows no ^{13}C – ^{13}C dipolar splittings under normal conditions due to the low natural abundance of ^{13}C and the poor solubility in liquid crystalline media.

5 CONCLUSIONS

The above discussion demonstrates that the NMR spectra of systems oriented in mixtures of liquid crystals of opposite diamagnetic anisotropies exhibit interesting features that lead to novel applications of NMR.

1 INTRODUCTION

The analysis of NMR spectra of aligned liquid crystalline samples provides insight into the structure and dynamics of the molecular constituents or of dissolved molecular probes. However, the NMR spectra of ordinary liquid crystal samples are often too complicated to analyze. This is because the presence of proton-proton dipolar couplings renders the system strongly coupled. Substitution of the protons by deuterons might simplify the analysis, although the assignment of the signals remains uncertain. Separated local field methods for liquid crystals provide a tool to measure and/or assign in a straightforward manner interactions such as heteronuclear dipolar couplings or quadrupolar couplings in deuterium labeled compounds.

1.1 Relevance of the Separate Local Field Approach for Liquid Crystals

The dipolar coupling between protons is a long-range interaction, which is still active over several Angstroms. Any organic molecule is thus a system of mutually coupled spins, the size of which can become rather large already for small molecular weights. The spectral complexity increases accordingly, the number of lines for a system of N coupled spin 1/2 being

$$n_l = \left(\frac{2N}{N-1} \right)$$

For example, a system of 6 coupled spin-1/2 nuclei leads to 763 transitions. Molecular symmetry may reduce this number, but even so the problem of solving the proton spectrum becomes untractable for $N \sim 10$, where $n_l > 10\,000$. Conversely, the spectrum of diluted spins, such as ^{13}C , can be well resolved as, under ^1H decoupling, it is dominated by its chemical shift, the next NMR active neighbors being far in space. The separation of the local fields is a multi-dimensional NMR method in which the chemical shift of a

diluted nucleus can be used to spread out other interactions using a two-dimensional scheme. Heteronuclear interactions can be measured and/or assigned in the second dimension in a more straightforward fashion. The ability to assign a coupling to a determined internuclear vector is not a trivial matter in liquid crystalline samples. In these materials, the size of the interaction depends on the molecular structure and orientation. In the absence of direct knowledge on the coupling partners, the assignment is carried out on the basis of the expected length and/or orientation of internuclear vectors. This approach yielded often reasonable results. However, labeling of the coupling partners by their chemical shift constitutes a sounder approach that may help for uncertain cases. Since the assignment obtained this way is model-free, the information obtained can be used to determine fine aspects of the molecular dynamics.

2 DEFINITIONS

2.1 Liquid Crystal Hamiltonians

The interactions measured by NMR in liquid crystals are average quantities, due to the presence of molecular motion:

$$\langle A \rangle = \int A(\Omega) f(\Omega) d\Omega \quad (1)$$

where the integral runs over the orientational coordinates and $f(\Omega)$ is the associated probability distribution function.

Due to motional averaging the NMR spectrum of magnetically or mechanically aligned samples, although still anisotropic in nature, does not show a powder-like line shape, but it is rather constituted of narrow lines.

In the case of molecules with some degree of internal flexibility, the average must be extended over internal (ϕ) and external orientational coordinates (Ω):

$$\langle A \rangle = \int A(\Omega, \phi) f(\Omega, \phi) d\Omega d\phi \quad (2)$$

These average quantities can be interpreted in terms of molecular dynamics, or as constraints in modeling an overall anisotropic potential, $U(\Omega, \phi)$, such as $f(\Omega, \phi) \propto e^{-U(\Omega, \phi)/kT}$ (see **Liquid Crystalline Samples: Structure of Nonrigid Molecules**, Volume 4).

The relevant NMR interactions for organic molecules (or for the organic part of an organometallic moiety) are the chemical shift, indirect scalar coupling and the magnetic dipolar coupling. Deuterium labeling is often used to simplify the spectra. In this case, the dominant interaction becomes the nuclear electric quadrupolar coupling. Chemical shift and quadrupolar couplings are often used to investigate the local order, especially as a function of the temperature in a phase diagram, capitalizing on the orientational dependence of these interactions (see **Liquid Crystalline Samples: Carbon-13 NMR**, Volume 4 and **Liquid Crystalline Samples: Deuterium NMR**, Volume 4). The dipolar coupling may play a similar role, with the additional important property of being an extremely sensitive probe of the internal dynamics, due to its dependence on the internuclear distance. In this respect, dipolar couplings between nuclei far apart are particularly useful, as their distance is more likely to vary between molecular conformations.

2.2 The Separate Local Field (SLF) Principle

The local field separation is a heteronuclear correlation two-dimensional experiment, first introduced by Waugh and coworkers.^{1,2} As mentioned earlier, the resolution of the chemical shift dimension of a diluted nucleus is exploited to spread out (and measure) anisotropic interactions. A successful implementation of this scheme can be achieved only if the local fields relative to each probe nucleus are magnetically isolated from each other. That is to say, the corresponding 1D spectrum has to be the sum of distinct contributions, rather than the complicated one arising from a strongly coupled system. In practical terms, a prerequisite is the removal of long-range contacts, which in liquid crystals are provided by proton-proton dipolar couplings. The latter need to be effectively and selectively suppressed in order to implement any SLF scheme. This can be achieved either by employing dedicated pulse sequences (see **CRAMPS**, Volume 3), or chemically, by deuterium substitution. Each one

of the mentioned options gives rise to a family of local field experiments, one to measure and assign short-range and long-range heteronuclear dipolar couplings, and the other to assign quadrupolar couplings.

3 METHODS TO MEASURE DIPOLAR COUPLINGS

3.1 Basic Pulse Sequences

The local fields concerned in this case are heteronuclear dipolar couplings (e.g., C–H or P–H). The measured quantity is actually a combination of a dipolar and a scalar interaction, as they share the same operator dependence. In the case of an isolated pair, the splitting of the transitions due to the heteronuclear coupling is shown in equation (3) (see **Liquid Crystalline Samples: Carbon-13 NMR**, Volume 4),

$$A = (2D + J) * f_S \quad (3)$$

Figure 1 Pulse sequence schemes for “dipolar” separate local field experiments. (a) SLF pulse sequence. After excitation of S coherence with a $\pi/2$ pulse, evolution is allowed to occur under the pure I–S heteronuclear interaction (t_1). Other interactions are removed either by a simultaneous pair of π pulses on I and S (chemical shift) or by a dedicated irradiation scheme for selective I–I decoupling (see text). Typically, a multiple-pulse sequence is used for this purpose. This latter is encased by two extra pulses to tilt the relevant density matrix into suitable directions to achieve maximum efficiency when integrated with the other elements of the sequence. High-power I–S decoupling assures that the S chemical shift is the only active interaction during acquisition (t_2). (b) PELF (PDLF) pulse sequence. I nucleus coherence is first excited by a $\pi/2$ pulse, then allowed to evolve (t_1) under I–S coupling in analogy to the previous scheme; this same coherence is then cross-polarized onto nucleus S, which is observed during acquisition under high-power I–S decoupling. Some published sequences may include other optional elements, such as a presaturation pulse train on S or z-filters to facilitate pure-phase 2D spectroscopy. Adapted from Ref.⁸, reproduced by permission of the American Chemical Society

where f_S is the scaling factor associated with the use of a multiple-pulse sequence to remove the homonuclear couplings. The largest known theoretical value for f_S is about 0.575.^{3,4}

In the case of a diluted nucleus S, such as a carbon or a phosphorous atom, surrounded by many abundant (proton) I nuclei, two different ways to measure I–S coupling have been proposed (Figure 1).

In the first scheme (Figure 1(a)), the heteronuclear dipolar Hamiltonian is allowed to act on carbon coherence (created by a pulse). The relevant operators carrying the information about the heteronuclear coupling will be of the form shown in equation (4).

$$S_x \prod_k \cos(A_k t) + \sum_k 2S_y I_z \sin(A_k t) \quad (4)$$

In the second half of the sequence, only the first term is observed, under proton decoupling. In the example of an organic molecule, the presence of N protons thus split the carbon spectrum into a complex multiplet with 2^N lines. An example of application to the liquid crystal 5CB (4-*n*-pentyl-4'-cyanobiphenyl) is shown in Figure 2(a).⁵

This approach was the first to be introduced, following the original idea of local field separation as proposed by Waugh.^{6,7} In the case of liquid crystal applications, this pulse sequence has been going under the simple acronym of SLF (Separate Local Field) experiment. Each trace of the 2D diagram is a combination spectrum arising from sums and differences of several heteronuclear couplings. A simultaneous fitting of all lines has to be performed in order to extract the values of the interactions. This part of the analysis may prove difficult, as it requires the resolution of all lines, especially the many ones in the center of the spectrum.

Another possible implementation of the local field separation consists in allowing the heteronuclear couplings to act upon proton coherence (Figure 1(b)).⁸ In this case, the operators carrying the information on the heteronuclear coupling are in the form shown in equation (5),

$$\sum_k I_x \cos(A_k t) + \sum_k 2I_y S_z \sin(A_k t) \quad (5)$$

as it is unlikely for any proton k to have more than one coupling partner of the diluted species. The first term in equation (5) is transferred via cross-polarization into observable S_x terms. The spectrum is thus a sum of doublets, with a total of $2N$ lines. This second approach has several advantages. Firstly, the reduced number of lines ($2N$ vs 2^N) translates into a better S/N. Moreover, it is easier to measure dipolar coupling, as each doublet in the traces splits according to equation (1) (see Figure 2(b)). The lack of resolution on part of the spectrum does not affect the measurement of the other couplings. For example, in the case of C–H pairs, the measurement of the largest splitting, corresponding to directly bond partners, yields information equivalent to deuterium NMR of labeled compounds, but without chemistry required.⁹ This second implementation was originally dubbed proton-detected local field (PDLF) then changed to proton-encoded local field (PELF) to avoid confusion since the actual detection in practical cases occurs on the diluted nucleus.^{5,10,11}

Figure 2 A comparison of the SLF and PELF methods for the nematic liquid crystal 5CB (4-*n*-pentyl-4'-cyanobiphenyl), the structure and ^{13}C NMR spectrum of which are reported on top. The left column shows traces of the 2D SLF experiment [Figure 1(a)] extracted at a chemical shift for a given carbon site. The right column (b) shows the equivalent for the PELF experiment [Figure 1(b)]. Note the different structure of the traces. SLF spectra are complex multiplets, while PELF spectra are the sum of doublets. Smaller long-range couplings produce the unresolved doublets in the center of PELF spectra. In both cases I–I decoupling was achieved by BLEW-48. Reproduced from Ref.⁵ by permission of Academic Press

3.2 Off Magic-Angle (OMAS) or Variable-Angle (VAS) Spinning Experiments

Spinning of nematic liquid crystalline samples in the presence of a magnetic field introduces an additional torque

to the nematic director due to the action of viscous forces. This effect competes with magnetic alignment due to the anisotropy of the magnetic susceptibility (see **Spinning Liquid Crystalline Samples**, Volume 7) and tends to orient the directors along the axis of rotation. The ‘viscosity’ alignment mechanism dominates when the spinning rate is in excess of a threshold value. This kind of alignment is possible only for a given range of subtended angles between the rotor axis and the magnetic field, below or above the magic angle, depending on whether the anisotropy of the magnetic susceptibility is positive or negative, respectively. Considering that anisotropic NMR interactions depend on their orientation with respect to the magnetic field, spinning of the sample can be used to scale down the size of the heteronuclear coupling. In the case of a nematic liquid crystal, the dipolar coupling becomes as shown in equation (6),

$$D' = D \frac{(3 \cos^2 \beta - 1)}{2} \quad (6)$$

where β is the angle subtended between the rotor axis and the magnetic field (see **Spinning Liquid Crystalline Samples**, Volume 7). The possibility of reducing the anisotropic interactions by this effect, particularly the proton-proton dipolar couplings, has been used to facilitate the suppression of the proton homonuclear couplings. PELF or SLF experiments can be performed under OMAS, and in some cases increased resolution has been observed.⁷ However, one should bear in mind that heteronuclear couplings are scaled down according to equation (6). An optimal OMAS (β) angle should be chosen in order to balance these two counteracting effects, especially if one is interested in measuring small long-range couplings. Local field experiments performed off magic-angle are often referred to as variable angle spinning (VAS) methods, since they can be performed, in principle, at different angles.

3.3 Accuracy and Precision of the Measurements

Many effects contribute to the experimental error on the measured couplings (variation of the local order, sample

inhomogeneity, etc.). A pervasive source of error, typical of local field experiments, is the difficulty to accurately assess the scaling factor f_s in equation (3). The latter is theoretically known, but often depends on experimental details such as the ratio of the dipolar coupling to the RF field. Moreover, the scaling factor may not be homogeneous throughout the spectrum, as it may depend on the offset.^{12,13} In the case of the SLF experiment (Figures 1 and 2(a)), either performed in a static or VAS scheme, all sources of error are mirrored by the goodness of the fit of the spectrum. In fact, the spectrum in this case is the product of combinations of many dipolar couplings involving different partners, and so the individual uncertainties propagate and combine into the line positions. Accuracy and precision of the measurements are directly related here. Conversely, precision for PELF schemes can be as high as the digital resolution of the spectrum, as the coupling is measured from the frequency difference of the lines of a doublet. This precision is expected to largely exceed the reasonable value of the accuracy. In the case when the RF coil in the VAS probe is oriented along the sample holder, the accuracy of the measurement can be evaluated by performing a series of VAS PELF spinning at different angles. By varying the rotor angle, the dipolar couplings will change according to equation (6), but the effective RF field will scale linearly. The consequent modulation of the ratio between the homonuclear proton-proton coupling and the irradiating field will affect the experimental scaling factor in a way that would mimic the variation in the effective RF field caused by the offset in a different part of the spectrum. The accuracy of the experiment can be thus inferred by a linear regression of the splitting $\Delta\nu$ measured along a series of VAS experiments to a combination of equations (5) and (6). Experimental errors measured this way showed a consistent value (about 5% in the case of MREV8) between SLF and PELF experiments.¹⁰

3.4 Efficiency of Homonuclear Decoupling Sequences

A crucial step toward achieving the best resolution in SLF experiments is to optimize the performance of the

Figure 3 3D extension of the PELF (PDLF) scheme of Figure 1(a). An extra dimension, corresponding to pure I chemical shift evolution, is achieved by combining I-I decoupling and a π pulse on S, which refocuses the heteronuclear I-S couplings. In the literature, two versions of this scheme have been implemented: one in which evolution times t_1 and t_2 were incremented synchronously and the full 3D experiment. Adapted from Ref.¹¹ by permission of the American Chemical Society

proton homonuclear decoupling.^{9,12,13} Historically, MREV8 or BLEW48 were used, but more recent and better-performing sequences can be easily integrated into the method.^{9,14–16} Liquid crystal samples present the additional constraint that long, high-power pulse trains may induce thermal gradients, which could perturb the local order of the sample. This can be a serious nuisance in the case of liquid crystalline phases that are stable only over a narrow range of temperatures. Fortunately, the size of the proton-proton coupling to be removed is scaled down by the molecular motion, so that it is often not necessary to employ more than moderate power levels for homonuclear decoupling. If possible, a sequence providing a large and homogeneous (as a function of the offset) scaling factor should be chosen.

3.5 3D Methods for Long-range Couplings

Long-range dipolar couplings are particularly useful as constraints in the study of the dynamics of flexible molecules, as they are extremely sensitive to conformational modifications. It is apparent from Figure 2(b) that the PELF method can provide a reliable measurement for long-range couplings, associated to the many resolved doublets toward the center of the traces. However, these interactions cannot be fully assigned, as the carbon chemical shift only provides a label for one of the partners of the coupling. A possible ploy to avoid recourse to geometrical models is the ‘natural’ development to a three-dimensional extension of the PELF method, adding as a third dimension the proton chemical shift (Figure 5), which makes the assignment complete.^{17,18} Although in principle being the perfect method, the performance of the 3D version of the PELF relies upon a good resolution of the proton spectrum. It is thus relatively easy to distinguish couplings between a given carbon and well-resolved protons, for instance belonging to an aromatic or aliphatic part of the molecule. Another good candidate, as shown in Figure 4, is the tail of an aliphatic chain, as the methyl proton resonance is usually well isolated. Couplings between partners of up to 4 bonds away can be measured in the case of the liquid crystal 5CB (Figure 3). On the other hand, assignment of couplings inside an aliphatic chain may prove more difficult.

4 METHODS FOR QUADRUPOLEAR COUPLINGS (DECOR)

Spectral simplification in organic liquid crystals can be achieved by isotopic substitution of protons with deuterium (see **Liquid Crystalline Samples: Deuterium NMR**, Volume 4). The spectrum of a spin-1 nucleus is dominated by the quadrupolar interaction, and the dipolar couplings between hydrogens are scaled down by a factor of about 36 (by γ_H^2/γ_D^2) upon isotopic substitution. Consequently the spectrum is constituted of quadrupolar doublets, split by twice the quadrupolar frequency ω_Q , with residual dipolar couplings acting as a fine, often unresolved structure. The deuterium spectrum is usually well resolved for molecules of moderate size. However, similar to the case of dipolar spectra, the assignment of uniformly labeled compounds is obtained on the basis of geometric arguments. In the case of molecules with some degree of internal flexibility, such an assumption implies prior knowledge of the average molecular shape in solution and its correlation with

Figure 4 3D PELF spectrum of the aliphatic region of the liquid crystal 5CB. The ω_2/ω_3 plane projection yields an heteronuclear correlation spectrum (upper left). In the proton dimension, the α and ω sites are well resolved, while all other signals overlap. The methyl protons show dipolar contacts with several carbon atoms, the details of which are unveiled in the corresponding ω_2 plane (upper right), in which the size of the $H_\omega-C^X$ ($X = \alpha, \dots, \omega$) interaction is proportional to the splitting (equation (1)). The corresponding traces are shown in the lower part of the figure. The small $H^\omega-C^\beta$ coupling, corresponding to a partially unresolved splitting, was evaluated by fitting of the line shape. the orientation. An independent way of assigning a deuterium site to a specific C–D bond is to use the ^{13}C chemical shift as a label, analogously to the PELF idea for heteronuclear dipolar couplings. Deuterium-carbon correlation can be achieved using a pulse scheme analogous to PELF (Figure 5), but simplified because of the absence of a strongly coupled network of deuterium nuclei.^{19,20}

This method has been dubbed DECOR (DEuterium CORrelation spectroscopy). The (optional) 180 degree pulse on deuterium during t_1 (Figure 5) is sufficient in this case to remove the (reduced) C–D dipolar coupling. The latter may otherwise be revealed (and measured) as a splitting or line broadening (see Figure 4) in the DECOR spectra.

Besides providing a way for assigning deuterium spectra, this technique can be helpful in measuring quadrupolar couplings that are not resolved in the one-dimensional spectrum.

Figure 5 Pulse sequence for the separate local field experiments involving quadrupolar nuclei. In liquid crystals this concerns assignment of quadrupolar couplings in deuterated samples, and for this reason it was dubbed DECOR (DEUTERIUM CORRELATION spectroscopy). The first dimension (t_1) is simply the deuterium (I) evolution, with an optional π pulse to refocus I–S (i.e., deuterium–carbon) couplings and I chemical shift to obtain a purely quadrupolar dimension. Acquisition takes place on the S spins under I–S decoupling, after cross polarization. The latter requires special care to insure a match condition sufficiently broad to cover all C–D pairs. In the example in Figure 6, only one of the two lines of the quadrupolar doublet was used for the transfer (single-quantum cross-polarization). Even with this restriction, variable-amplitude spin-lock was still required to further broaden the match condition. Adapted from Ref.¹⁹ by permission of the American Chemical Society

4.1 Deuterium to Carbon Cross-polarization

A delicate part in the DECOR pulse sequence is the cross-polarization step due to the large span of the deuterium spectrum, which defies the ability of a RF field to spin-lock the magnetization ($\omega_{\text{RF}} \ll \omega_{\text{Q}}$). Efficient cross-polarization with weak RF fields can be recovered by focussing on half of the symmetrical spectrum typical of the spin-1 deuterium. That is to say, only one of the two single-quantum transitions (i.e., one of the two lines of the doublet) is used to cross-polarize to the carbons, without loss of information. In fact, the main cause of spectral dispersion for a typical liquid crystal sample is the dispersion of the average quadrupolar couplings, essentially due to differences in mobility or average orientation of the molecular segments. The spectrum can be seen as two almost symmetrical groups of lines, in most cases well separated. In fact, single-quantum transitions are further shifted by the chemical shift and split by the dipolar coupling, which are usually much weaker interactions than the quadrupolar coupling ($\omega_{\text{CS}}, \omega_{\text{D}} \ll \omega_{\text{Q}}$). One can thus focus on half of the spectrum without losing any site resonance. The match condition for cross-polarization modifies accordingly: $\omega_{\text{S}} = \sqrt{2}\omega_{\text{I}}$.^{19,20} The spectral breadth of the ensemble of the SQ-transitions can still be too large to be effectively spin-locked ($|\omega_{\text{Q}}^{\text{max}} - \omega_{\text{Q}}^{\text{min}}| > \omega_{\text{RF}}$), depending on the experimental conditions.²¹ In the original experiment, a variable-amplitude cross-polarization scheme was necessary to broaden the match condition enough to achieve a homogeneous transfer over the entire spectrum.²²

As a consequence of the use of only one SQ transition, in the DECOR 2D diagrams (see Figure 4) only half of the 1D deuterium spectrum correlates with the ^{13}C spectrum. This is sufficient to assign the deuterium spectrum, due to its mirror symmetry (neglecting to first order the effect of chemical shift).

4.2 Exploiting Long-range Correlations to Resolve Assignment Ambiguities

In some cases, the dipolar coupling between a directly bonded C–D pair and a pair of second neighbors may assume

Figure 6 DECOR spectrum of the aliphatic region of a fully deuterated sample of 5CB, using the pulse sequence in Figure 5. The deuterium frequency dimension shows only half of the characteristic quadrupolar doublets because of the selective single-quantum deuterium to carbon cross-polarization scheme used (see text). The effects of the 180 degree pulse on deuterium at $t_1/2$ are demonstrated by the further splitting of some of the peaks in the upper spectrum as compared to the lower one. The effect, as the C–D dipolar coupling, scales with the quadrupolar frequency, since the two interactions are co-linear. Reproduced from Ref.²⁰ by permission of the American Chemical Society

similar values, because of particular orientation effects. For instance, the C–D coupling of directly bonded pairs in the aromatic ring of perdeuterated 5CB is severely reduced as the bond aligns close to the magic angle with respect to the magnetic field. As a consequence, its size becomes comparable

with that of the coupling relative to next neighbors. A same quadrupolar signal in the deuterium dimension can thus correlate to two carbon signals in a DECOR experiment. This kind of ambiguity in the assignment can be lifted by using longer mixing times in the CP transfer, by which the search for correlations is pushed further to smaller couplings, and thus farther neighbors.

1 SURFACTANT STRUCTURES

1.1 Introduction

Amphiphilic liquid crystalline materials are most familiar as soaps or detergents in water. They are, perhaps, much less familiar as one of the fundamental building blocks of living materials.¹ It is, however, the ability of lipids spontaneously to generate the lipid bilayer membranes of cells that makes possible the functioning of life as we know it (see also *Bilayer Membranes: Deuterium and Carbon-13 NMR* and *Bilayer Membranes: Proton and Fluorine-19 NMR*).

Chemical compounds capable of forming liquid crystals are known as *mesogens*. Liquid crystals formed by heating a single compound are known as *thermotropic liquid crystals*, while those formed by solvation, i.e. dissolution of a solute in a solvent, are called *lyotropic liquid crystals*. The name 'liquid crystal' arises because, although the materials are fluids, they also have anisotropic properties, such as birefringence, that are usually associated with crystals. There are two main types of lyotropic liquid crystals. The first type arises from the action of an organic solvent on a polymer (see *Polymer Dispersed Liquid Crystals*). The second type of lyotropic liquid crystal is formed by the action of a solvent, usually water, on an amphiphile, and this type is the topic of this article (see also *Micellar Solutions and Microemulsions*). An amphiphilic substance has a dual nature—usually a headgroup which is hydrophilic (has an affinity for water), and a hydrocarbon chain which is hydrophobic (lacks an affinity for water). These properties lead to the formation of structured arrays of amphiphile aggregates, where the headgroups provide an interface between the water and the hydrocarbon chains and help keep the aggregates in solution.^{2,3} Examples of amphiphiles are detergents, flocculants, dispersants, and lipids.

Somewhat surprisingly, despite the apparently simple nature of the amphiphiles themselves, they form a rather complicated set of macroscopic structures.^{4,5} These structures are based principally on three motifs: spherical or semispherical arrays of limited size; cylindrically shaped arrays of finite cross section but of indefinite length; and planar arrays of indefinite extent in two dimensions but of limited thickness.

1.2 The Structural Motifs

There is a progression in structure associated with changes in the concentration of the amphiphile in water. In very dilute solution the amphiphiles exist essentially as individual ionic species that interact only transiently with each other. At a certain concentration, known as the critical micelle concentration, the amphiphiles aggregate into stable semispherical entities and give rise to the isotropic micellar solution. With a continued increase in amphiphile concentration a phase transition occurs, generally to the cylindrical or middle soap structure. The individual aggregates of this mesophase tend to, though do not necessarily,⁵ arrange themselves into a hexagonally-packed array and this is often referred to as the *hexagonal* or *H₁* phase. Occasionally a cubic-packed arrangement occurs, and this is known as the *rectangular* phase. Further increases in amphiphile concentration will cause an additional phase transition and the *neat* or *lamellar* (*L_α*) mesophase is formed. This structure generally persists into the truly crystalline state.

On occasion, before a phase transition to the cylindrical or lamellar structure occurs, the micelles pack together in a cubic-close-packed array to form a second type of isotropic phase. These tend to be highly viscous materials and are referred to as the *viscous isotropic* (*I₁*) phase. Two forms exist and correspond to body-centered-cubic or face-centered-cubic arrays. Often, aggregates of intermediate structure are formed. For instance, ribbon-like structures can be generated as an intermediate stage in the progression from cylindrical to lamellar arrays. Instead of a circular cross section as in the cylindrical phase, a cross section of the *ribbon* (*R₁*) phase reveals an ellipsoidal structure. Aggregate structures corresponding to the isotropic micellar mesophase and the three anisotropic mesophases are depicted in Figure 1.

Of particular interest, from the NMR point of view, are the intermediate structures formed from micelles. Incorporation of additional amphiphile into a micellar solution can cause a phase change to a structure in which the micelles become elongated to form cylindrically shaped micelles. These micelles are closely related to the cylindrical aggregates of the hexagonal mesophase but are of limited length. This intermediate structure is not necessarily adopted; instead, a phase transition may occur to disk-like aggregates that have a close resemblance to the components of the lamellar mesophase. These entities are thermodynamically well defined and undergo phase transitions to and from other aggregate structures and form optically uniaxial mesophases. In binary systems of amphiphile in water these two intermediate structures are not well known. However, they, are much more readily formed if an electrolyte or a long-chain aliphatic alcohol is added to the medium. In addition, it is often possible to induce phase transitions between these disk and cylindrical structures by changing the electrolyte concentration or decanol or water content. Occasionally, an intermediate structure is formed that is optically biaxial.⁶ Unlike the systems described previously, this latter mesophase has two unique axes and alignment occurs about both directors simultaneously. The structure of the biaxial phase is not known, but may well be a truncated form of the ribbon phase.

Additional structures are formed if the water of the mesophase is replaced by an organic solvent. In this event, the inverse phases are formed in which the organic region of the detergent solution is continuous and the residual water, ions,

Figure 1 Diagrammatic illustration of the four major structures formed by surfactant materials. Not all structures are formed for all amphiphiles. (a) The spheroidal entities that give rise to the isotropic micellar phase. (b) The cylindrical shaped aggregates of indefinite length that generate the hexagonal and cubic-close-packed mesophases. (c) The planar aggregate of indefinite extent in two dimensions that forms the lamellar mesophase. (d) The structure intermediate between the cylindrical and planar aggregates, which forms the ribbon phase

and amphiphile headgroups aggregate into discrete regions. This situation gives rise to the inverse micellar, cylindrical, and other phases.⁷⁻⁹ These materials, although of great interest, are not the topic of this article.

On consideration of the cylindrical structure of the elongated micelle, it is evident that a unique axis can be defined which runs lengthwise through the cylinder. Correspondingly, a unique axis can be defined that is perpendicular to the plane of the disk-like micelle. These axes are known as *directors*. Cooperative long-range interactions occur between micelles that cause the individual director axes to align with one another to form, in effect, microcrystalline regions. Within these regions, on average, all micelles have their directors aligned parallel to each other and the directors behave cooperatively.

Because fully extended hydrocarbon chains are long compared to their cross-sectional area, the diamagnetism associated with the molecular structure is anisotropic. The diamagnetic anisotropy is negative. This means that if hydrocarbon chains are fully or partially extended and subjected to a magnetic field, there is a tendency to align in the field with their

long axis perpendicular to the applied field. This tendency is enhanced when many alkyl chains can act together, as in the cylindrical or disk micelles. This effect is further enhanced because of the cooperative behavior between micelles. The net result is that when these types of amphiphilic solution are placed in a magnetic field, as in an NMR spectrometer, all micelles align with their directors parallel to each other. The result is a liquid that, in many respects, behaves as a single crystalline entity. These are called *nematic lyotropic liquid crystals*. The disk-like micelles align with the director axis perpendicular to the applied field to accommodate the diamagnetic anisotropy of the hydrocarbon chains. The cylindrical micelles align with their directors parallel to the applied field. It is, therefore, relatively easy to distinguish between these two mesophases with an NMR experiment. The two phases are designated as *nematic lamellar* (N_L) phase and *nematic cylindrical* (N_C) phase because of the close correspondence in structures between these and the lamellar and cylindrical phases. When in a magnetic field, the biaxial mesophase will

Figure 2 Diagrammatic illustration of the most commonly encountered mesophases that spontaneously align in an applied magnetic field. (a) The nematic cylindrical phase. (b) The nematic disk phase. (c) The cholesteric mesophase derived from a disk-like nematic phase

undergo simultaneous forces for alignment along both directors. This mesophase is designated the *nematic biaxial* (N_{BX}) phase. Neither the parent structures, the lamellar phase, the cylindrical phase, nor the ribbon phase orients in an applied field, because of their high viscosity.

If the amphiphile of the nematic mesophase contains a chiral center, or if a chiral additive is added to the mesophase, asymmetric interactions occur within the micellar structure. The result of these interactions is the generation of a chiral micelle. Because of the nematic character of the solution, the micelles still align in a magnetic field. However, the additional asymmetric long range interaction between the chiral micelles introduces a helical twist into the mesophase structure. These special nematic mesophases are known as *cholesteric lyotropic liquid crystals* and are denoted by Ch_C or Ch_L , to designate their origin from cylinder-like or lamellar-like precursors, respectively. Figure 2 depicts the structural units of the two common types of nematic mesophase and also a cholesteric modification derived from a nematic disk phase. The close structural correspondence between these aggregates and those shown in Figure 1 is exemplified by the drawings in Figure 2.

1.3 The Building Blocks

On the molecular scale there are only small differences between the aggregate structures of the various amphiphilic materials. These differences arise from the motional restrictions imposed by surface curvature and from the packing of the hydrocarbon chains within the various structures. The motional properties of the various components of the individual aggregates are addressed in other chapters of this Encyclopedia (see *Amphiphilic Liquid Crystalline Samples: Nuclear Spin Relaxation* and *Liquid Crystalline Samples: Diffusion*). The influence of charge, electrolyte, and changes in counterions will be discussed briefly here, as will the effects of combining amphiphiles of different headgroup or charge state.

On a microscale, these amphiphilic materials all contain three distinct regions: the aqueous region, the interface region, and the organic region. The aqueous region contains the water, the counterions to the charged amphiphiles, and any added electrolyte. This region serves to mediate the reactions occurring between the aggregates. The headgroups of the amphiphiles, in combination with the bound counterions and associated water, form the interface region. The headgroups of added amphiphiles, such as the hydroxyl group of decanol, will also be located in the interface and the interface separates the aqueous region from the organic region of the system.

The alkyl group of the amphiphile is located in the interior of the aggregates. Hydrophobic additives are also located in this region. This and the other two regions of the lyotropic system are all readily studied by means of NMR techniques.

2 NUCLEAR MAGNETIC RESONANCE

NMR has provided an excellent tool for the study of lyotropic liquid crystals.^{4,10–12} The usefulness of this tool lies mainly in its ability to observe directly the individual components of the mesophase. On the other hand, the liquid crystalline behavior of the mesophase itself strongly enhances the power of NMR spectroscopy. Because the motions of the amphiphilic aggregates are anisotropic there is incomplete motional averaging of various interactions, and this leads to NMR observables that give details about the properties of the amphiphilic material.

The two interactions most utilized for the study of anisotropic systems are the dipolar coupling and quadrupole splitting. Of these two, the dipolar coupling has been utilized mostly for studying the structure of solutes (see *Structure of Rigid Molecules Dissolved in Liquid Crystalline Solvents*), while the quadrupolar interaction has allowed many of the details of the structure of lyotropic mesophases to be determined.

2.1 Quadrupolar Interactions

2.1.1 Quadrupole Splittings

In the generally observed case when a nucleus of spin $I > \frac{1}{2}$ is subjected to an anisotropic environment, the NMR spectrum is split into $2I$ equally spaced transitions with an interaction energy B given by

$$B = \frac{eQ \cdot V_{zz}}{h4I(2I-1)} [3S_{zz} + \eta(S_{xx} - S_{yy})] \quad (1)$$

where eQ is the nuclear quadrupole moment, eQV_{zz}/h is the quadrupole coupling constant, η represents the asymmetry in the electric field gradient $\mathbf{V}$, and h is Planck's constant. The S_{ii} terms represent the alignment of the nuclear fixed coordinate system in the magnetic field of the NMR spectrometer. The observed spacing in the NMR spectrum, $\Delta\nu$, is equal to $2B$.

The coordinates of the electric field gradient tensor are chosen so that $|V_{zz}| \geq |V_{yy}| \geq |V_{xx}|$, since $V_{xx} + V_{yy} + V_{zz} = 0$. The asymmetry parameter $\eta = (V_{xx} - V_{yy})/V_{zz}$ takes the values $0 \leq \eta \leq 1$; $\eta = 0$ corresponds to the special case of axial symmetry, while the condition that $V_{xx} + V_{yy} + V_{zz} = 0$ means that if the nucleus is located at a position of cubic or higher symmetry the quadrupole splitting vanishes. As a consequence of this, the observation of quadrupole splittings from ions such as Na^+ , Li^+ , Cl^- , or other similar species means that distortions from high symmetry occur.

2.1.2 Quadrupolar Induced Relaxation

Relaxation of quadrupolar nuclei is, even for nominally spherical ions such as Na^+ , K^+ , Cl^- , or Br^- , dominated by the interaction between the nuclear quadrupole moment and the fluctuating electric field gradients at the nucleus (see *Amphiphilic Liquid Crystalline Samples: Nuclear Spin Relaxation*). The relaxation rate $(1/T_1)$ is given by

$$\frac{1}{T_1} = \frac{3}{40} \frac{2I+3}{I^2(2I-1)} \left(\frac{eQV_{zz}}{\hbar} \right)^2 \tau_c \quad (2)$$

where the asymmetry in the electric field gradients is ignored. τ_c is the correlation time for the fluctuation in the orientation of electric field gradient in the magnetic field. This expression is valid in the case when fluctuations are much faster than the nuclear precession frequency, i.e. when $\omega_0\tau_c \ll 1$.

Ion binding in amphiphilic materials has generally been studied by relaxation techniques in order to obtain information concerning the motional properties of the ions in the interface. In anisotropic systems, such as nematic lyotropic liquid crystals, the quadrupolar nucleus gives rise to a quadrupole splitting in the NMR spectrum, the origin of which is the same as that leading to quadrupolar relaxation.

2.1.3 Quadrupolar Splittings from Pseudospherical Ions

The observation of quadrupolar splittings from alkali metal or halide ions shows that these materials have nonspherical components in their structures that have lower than tetrahedral symmetry. For the most commonly observed case, the

quadrupole splitting is small compared with the Zeeman splitting. Consequently, it is 'first order' and is given by equation (1). However, it is generally assumed that the distortions of the solvated ions which give rise to the quadrupole splitting are symmetric so that the electric field gradient tensor has rotational symmetry. Under these circumstances, the splitting $\Delta\nu$ is given by

$$\Delta\nu = \frac{3eQV_{zz}}{h2I(2I-1)} S \quad (3)$$

which can be written in terms of a quadrupole coupling constant Q equal to eQV_{zz}/h , so that

$$\Delta\nu = \frac{3}{2I(I-1)} QS \quad (4)$$

The quadrupole coupling constant Q and the order parameter S cannot be separated unambiguously for ions such as those of interest here. This separation, however, can be accomplished in complex systems where dipolar couplings are present. Figure 3 shows a typical NMR spectrum obtained from a quadrupole split resonance, in this case of the Cs^+ ion. The spectrum is characterized by $2I$ transitions of repeated spacing $\Delta\nu$.

Ions such as the halides, alkali metals, or other monatomic species are highly symmetric species surrounded by a solvent shell. The distortions that lead to the observation of quadrupole splittings occur primarily by two mechanisms. Specific binding of the ion to sites within the amphiphilic system can occur. Under these circumstances the binding gives rise to electric field gradients about the nucleus which result in the quadrupole splitting.¹³ A second means of distorting the solvation shell is for it to undergo anisotropic nonbonding interactions with its environment. Since the interaction forces are fixed in direction, the nucleus together with its hydration shell (although tumbling freely) is still affected by these forces, which distort the solvent shell. The direction of distortion is constant and the result gives rise to the splitting.¹⁴ Both these mechanisms are possible for most amphiphilic systems. Furthermore, more than one specific binding site could well occur. The product,

Figure 3 A ^{133}Cs NMR spectrum (52.4 MHz) of the Cs^+ ion in a nematic mesophase prepared from cesium decyl sulfate, decanol, and water. The observation of quadrupole splittings from this ion is consistent with it undergoing strong binding interactions in the interface region of the nematic (N_L) mesophase

QS , in equation (4) can be expected to be reasonably constant for any particular binding site, but different from one site to the other. If chemical exchange is fast compared with the difference of these terms for all sites involved, an averaged quadrupole splitting will be observed as described by

$$\Delta\nu = \sum_i X_i \Delta\nu_i \quad (5)$$

where X_i is the mole fraction of ions in site i , and $\Delta\nu_i$ is the corresponding quadrupole splitting. As it is possible that $\Delta\nu_i$ for any particular site i can be opposite in sign from $\Delta\nu_j$ for a second site j , then the observed splitting can be zero. A consequence of this is that quadrupole splittings might not be observed in some anisotropic systems, even though the nuclear relaxation is clearly quadrupole dominated.

3 THE MICROSTRUCTURE OF LYOTROPIC MESOPHASES

As mentioned previously, lyotropic mesophases contain three regions, each of which has distinct chemical properties. The three regions are the interstitial aqueous region, the interface region, and the organic region. All regions have been studied by NMR techniques.

3.1 The Interstitial Region

The interstitial region of a lyotropic mesophase consists mostly of water with some counterions. Additives, such as electrolyte or water soluble organic materials, will be dispersed throughout this region.

The interstitial region appears to be nearly isotropic in character. Dipolar couplings between organic co-ions (ions with the same charge as the amphiphile, for instance acetate in a sodium decyl sulfate mesophase) and other hydrophilic additives such as methanol, are quite small. Similarly, quadrupole splittings from inorganic co-ions are much smaller than when they are in solution as counterions. There must be some anisotropic character of the water region, but in general the effects are small. This anisotropy will be minimal for the mesophases of high water content, such as the nematic and cholesteric materials, but will be substantial for some of the low water content lamellar phases. Recent molecular dynamics simulations agree with this picture of the interstitial region, suggesting that the bulk properties of water are quickly attained as the water diffuses from the interface region of a membrane.¹⁵ This view has also been supported by self-diffusion measurements in liquid crystalline materials.¹⁶

3.2 The Interface Region

The interface region is characterized by three components. These are the headgroup of the amphiphile, the counterions that balance the charge, and the associated water. This region is frequently referred to as the *Stern layer*.

3.2.1 The Headgroup

A number of headgroups have been studied by NMR spectroscopy, the most informative one probably being the headgroup in the potassium *N*-dodecanoyl-L-alaninate amphiphile. Other headgroups that have been studied include pyridinium and trimethylammonium. The studies show that, as a general rule, the overall orientational order of the headgroup is comparable to that of the adjacent methylene segments of the attached hydrocarbon chain.

The headgroup of potassium *N*-dodecanoyl-L-alaninate contains a chiral center, and therefore this amphiphile gives rise to a cholesteric mesophase. Studies of this amphiphile have revealed a direct link between rotational isomerization within the headgroup of the amphiphile and the overall headgroup alignment. Furthermore, a linear correlation between the alignment of the headgroup and the twist (inverse pitch) of the helical axis of the phase was observed for this system. It was also found that the quadrupole splitting from the counterions in the mesophase was directly proportional to the alignment of the headgroup.¹⁷ These observations established that there is a direct connection between the molecular behavior (rotational isomerization) of the amphiphile and the macroscopic generation of a helical axis, and clearly showed that structural modifications within the Stern layer have a direct influence on the properties of the mesophase itself.

Often, a long-chain alcohol is added to an amphiphilic solution in order to modify the Stern layer and to cause phase changes. An alcohol frequently used is 1-decanol. Addition of decanol serves to promote the formation and to extend the range of the nematic mesophase. The role of decanol is not well understood, but the hydroxyl group seems to act as a spacer between headgroups; it allows headgroups to be spaced farther apart while simultaneously promoting a hydrogen-bonded water network throughout the interface. Decanol can often be replaced by other long-chain alcohols, decylamine or even amphiphiles carrying a charge of sign opposite to that of the primary amphiphile. Decanol is often the component of choice simply because it is innocuous, easy to work with, and readily purified.

3.2.2 Ion Binding

A procedure commonly employed in order to modify the interface region is to change the counterions. Such a modification is frequently sufficient to cause large changes in the mesophase structure, often resulting in phase transitions, for example from cylindrical to lamellar or lamellar to nematic.^{18–20} These changes are clearly associated with the interactions specific to the type of counterion employed.

The NMR methods commonly employed to study counterion interactions are relaxation (see *Amphiphilic Liquid Crystalline Samples: Nuclear Spin Relaxation*) and self-diffusion studies (see *Liquid Crystalline Samples: Diffusion*), and observation of the nuclear quadrupole splittings. The most commonly studied ions are the alkali metal and halide ions, although the interactions of transition metal complexes are attracting increasing attention.²¹ The relaxation time and self-diffusion studies have shown that the counterions undergo fast translational motion within the interface and exchange rapidly between the free and bound states. The details of the interface structure have emerged from utilization of the

quadrupole splitting of counterions. Probably the most salient result of the NMR studies was the finding that the number of headgroups involved in binding counterions was counterion specific.²² For instance, in a nematic dodecanoate mesophase, the lithium cation was held by two amphiphiles, the sodium ion by three, and the larger alkali metal ions by four amphiphiles. Halide ions showed a similar behavior in their binding to alkyltrimethylammonium amphiphiles. This chemistry, to a large extent, will account for the influence that the counterion has on the phase behavior of lyotropic mesophases.

3.3 The Organic Region

Studies of the aliphatic region of surfactant aggregates have concentrated on the ^{13}C relaxation times of the carbon signals for isotropic materials, ESR studies of nitroxide-labeled amphiphiles, and deuterium studies of deuterium-labeled amphiphiles for the anisotropic phases. The power of the ^{13}C relaxation studies and the deuterium NMR studies lies in their ability to extract an order parameter for the individual positions along the aliphatic chain.

3.3.1 The Deuterium Order Parameter

NMR spectra from deuterium nuclei in anisotropic systems are dominated by the deuterium quadrupole splitting [equation (1)] which for a spin-1 nucleus is given by equation (6) (see also *Liquid Crystalline Samples: Deuterium NMR*):

$$\Delta\nu = \frac{eQV_{zz}}{2h} [3S_{zz} + \eta(S_{xx} - S_{yy})] \quad (6)$$

The deuterium quadrupole coupling constant eQV_{zz}/h is often referred to as Q_D , the D specifying deuterium. Q_D is close to 170 kHz for the C–D bonds of methylene groups. Although η can be significant for quadrupolar nuclei other than deuterium, it is generally small for deuterium, and for most applications can be neglected. The various S_{ii} terms in equation (6) are order parameters describing the alignment of the electric field gradients, about the deuterium nucleus, in the magnetic field of the NMR spectrometer. For deuterium attached to carbon, the major axis of the electric field gradient, V_{zz} deviates only slightly from the C–D bond and, consequently, S_{zz} is equal to S_{CD} . With η being negligible, equation (6) can be rewritten as:

$$\Delta\nu = \frac{3}{2} Q_D S_{CD} \quad (7)$$

The parameter S_{CD} is an average value given by:

$$S_{CD} = \frac{1}{2} (3 \cos^2 \theta - 1) \quad (8)$$

where θ is the instantaneous angle between the magnetic induction $\mathbf{B}_0$ and the bond axis vector. An interesting property of the order parameter is that terms for motional averaging which result from the occurrence of fixed angles, for instance a precession about an axis a at the angle γ , can be readily extracted:

$$S_{CD} = \frac{1}{2} (3 \cos^2 \gamma - 1) S^0 \quad (9)$$

S^0 provides a measure of the alignment of the C–D bond resolved along the axis a . This process can be repeated for all such rigid body motions until an order parameter is obtained which reflects the alignment that would be observed if the C–D bond were directed preferentially along the magnetic field of the NMR spectrometer. The effects of a motion such as translation about the axis of a cylinder are thus readily accounted for.

3.3.2 The Order Profile

Investigation of the properties of hydrocarbon chains in liquid crystalline systems has depended to a large extent on the behavior of the observed order parameter as a function of position along the hydrocarbon chain. Early work in this area focused on the study of spin-labeled fatty acids and their derivatives.²³ It was found that the alignment of the spin label decreased in an exponential fashion with its position along the hydrocarbon chain, counting from the headgroup to the terminal position of the chain. It was soon found that the spin label was a poor reporter of the motion of n -alkyl hydrocarbon chains.²⁴ Deuterium quadrupole splittings from deuterated hydrocarbon chains showed not an exponential decrease in splitting with position, but rather a region of splittings of relatively constant magnitude extending over a high proportion of the chain length followed by a gradual decrease in quadrupole splittings. Figure 4 shows some

Figure 4 Deuterium quadrupole coupling splittings plotted as a function of methylene position for three different amphiphiles of a mixed detergent nematic (N_L) phase prepared from potassium dodecanoate, decyltrimethylammonium bromide, decanol and sodium bromide. (a) 90 mol% dodecanoate in total detergent; (b) 35 mol% dodecanoate in total detergent. For details see Lee et al.²⁸

excellent examples of this behavior. Several points are made obvious by this figure. The first point is that the plateau region is not necessarily particularly flat. Secondly, the behavior of quadrupole splittings with position along the chain is highly headgroup specific, so much so that it almost serves as a signature. A third point which can be made from Figure 4 is that the magnitude of the splitting which defines the plateau region is also headgroup specific. These characteristics of the hydrocarbon chain quadrupole splitting profile make it clear why spin labels are such poor probes of chain motions. As is obvious from Figure 4, changing the headgroup is sufficient to cause changes in the quadrupole splitting of 40% or more. Clearly, these effects are a result of the different interface interactions associated with those headgroups. Changes in the length of the hydrocarbon chains has a minimal effect on the quadrupole splittings throughout the regions that are comparable.²⁵ Recent studies of a sodium octanoate phase showed an essentially identical behavior.²⁶ The quadrupole splittings give the order parameter directly from equation (7) and the known value of Q_D . The quadrupole splitting (or alternatively S_{CD}) when plotted as a function of the methylene group position is generally referred to as an 'order profile'. As mentioned above, this profile is highly headgroup specific and it can be nearly flat or can show large deviations from flatness.

There are various aspects of the order profile which provide information concerning the dynamic properties of the hydrocarbon chain (see *Liquid Crystalline Samples: Structure of Nonrigid Molecules*). The magnitude of the order parameter itself is in some regards highly misleading, since contributions to S from rigid body motions may not be properly accounted for, as is clear from the study of relaxation times. Indeed, rigid body motions may well be, and probably are, different from one component of a bilayer to another. To circumvent this problem, ratios of quadrupole splittings, usually with the terminal methyl group being used as the reference, can be obtained.

In the event that a hydrocarbon chain is rigid and rotating freely about the long axis, the ratio of deuterium splittings of the methylene groups to methyl groups would be about 3.0, assuming only small distortions from tetrahedral geometry. With an increase in mobility of the terminal position with respect to the initial positions, the ratio of splittings becomes larger than 3.0 and, depending on internal motions, the plateau will no longer be flat. The closer the ratio of the plateau splitting to the methyl group splitting is to 3.0, the more the molecule behaves as a rigid entity. The number of carbon atoms over which the plateau extends is a further measure of this, as is the flatness of the plateau region. Figure 5 demonstrates the simultaneous changes of these three parameters as various amphiphiles are incorporated into a progressively less restrictive bilayer (bottom to top traces). Figures 4(a) and 4(b) show the quadrupole splittings corresponding to the 90 and 35 mol% potassium dodecanoate, respectively, in Figure 5. It is clear that the hydrocarbon group of the amphiphile with the larger quadrupole splittings (decanol) behaves least like a rigid rapidly rotating chain. Even though it is apparently the most highly aligned of the mesophase components, internal *cis/trans* isomerization about the C–C bonds is not as restricted as for the other two amphiphiles. The motions that cause the deviations of the plateau from flatness have their origins in the specificity of anchoring of the polar headgroup in the interface. These

Figure 5 Quadrupole splitting profiles for the three components of a mixed amphiphilic nematic mesophase showing the effects of changes in composition. The mole per cent KC_{12} refers to the molar proportion of potassium dodecanoate in the total of potassium dodecanoate plus decyltrimethylammonium bromide. The mesophase system corresponds to that in Figure 4. (a) Decyltrimethylammonium; (b) decanol; (c) dodecanoate

motions are presumably the fast motions which are observed from relaxation time measurements and which occur on a timescale of the order of 10^{-12} s.²⁷ The selectively restricted motional properties of the individual amphiphiles no doubt contribute strongly to the structure-building properties associated with different headgroups.

4 SUMMARY

The aggregate structures commonly associated with lyotropic liquid crystalline materials have been briefly discussed and the correspondence in structure between the nematic and non-nematic materials described. NMR spectroscopy has provided much of the information concerning the details of the various regions of these materials. The aqueous region of the mesophases is largely isotropic in character, but it can be used to attenuate and regulate the interactions between the amphiphilic aggregates through changes in water content or incorporation of electrolytes. It is the interface region that dominates the structural characteristics of the mesophase. The two main components of the interface, the counterions to the amphiphile headgroups and the headgroups themselves, strongly influence the properties of the interface and mesophase structure. In addition, the individual headgroups play a dominant role in the alignment and motional properties of the attached hydrocarbon chain. As a consequence, there is a marked heterogeneity in the behavior of the individual hydrocarbon chains when several amphiphiles are incorporated into a mixed mesophase.

1 INTRODUCTION

Surfactants are molecules with two distinctively different parts, one of which is hydrophilic and one which is hydrophobic. This feature of surfactants determines their properties in aqueous or oleic solutions. At low enough concentrations they form molecularly dispersed solutions. As the concentration is increased, they self-assemble into aggregates at a rather well-defined concentration, which is termed the *critical micellar concentration* (cmc) on account of the fact that the aggregates formed are termed *micelles*. As the concentration of surfactant is further increased, the aggregates crystallize into liquid crystalline phases with long-range order, the structures of which may vary rather substantially. The addition of a third component, giving rise to a water–oil–surfactant (where ‘oil’ is taken to be a generic term for an oleic component) system, results in an amazingly rich phase behavior, involving both liquid crystalline phases and liquid solution phases.

The present contribution will be concerned with the characterization by means of NMR techniques of two particular types of liquid solution of surfactant, the first being micellar solutions and the second being microemulsions. Having said this, we run into a problem of definition. How do we decide whether a particular solution belongs to one of these classes or perhaps to yet another class of solutions? Commonly, microemulsions are defined as thermodynamically stable solutions containing a surfactant (where ‘surfactant’ is a generic term for a single surfactant or mixtures of different amphiphilic molecules), water and oil. We shall adhere to this definition. Consequently, a micellar solution is one containing a surfactant and water (possibly with added salt) or oil, while the addition of oil or water to a micellar solution turns it into a microemulsion. Possible ambiguities of these definitions will be pointed out as we go along. [The name ‘microemulsion’ is somewhat unfortunate as it implies that the structure in the solution is one of discrete droplets of either water in oil (W/O) or oil in water (O/W). This is only partly true, as a rich variety of structures can indeed be found in addition to these two droplet structures. The literature is abundant with contributions which ignore this fact and only treat the two droplet structures.]

Studies of surfactant solution systems have had a central place in physical chemistry ever since the pioneering work of McBain at the beginning of this century,^{1–4} not least due to

the fact that these systems have important roles in a variety of applied processes. Questions asked pertain to the structure of the aggregates formed as well as the properties on a molecular level of the molecules comprising the systems.

It is fair to state that NMR has played a central role as a tool in tackling these questions, and much of our current understanding of surfactant solutions derives from NMR studies where two NMR methods have been especially important. The first of these is NMR relaxation studies, which have evolved to become an indispensable tool in studies of liquid surfactant solutions. The second one is measurements of self-diffusion coefficients by means of pulsed field gradients (PFG), an experiment which yields direct and easily interpretable information regarding many different aspects of surfactant solutions. In fact, our present understanding of the structure in microemulsions is to a large extent derived from PFG work in combination with various scattering approaches.

In the present article we discuss the two NMR approaches and describe applications which we consider to be those where NMR has contributed significantly to our present understanding of liquid solution phases of surfactants.

2 SELF-DIFFUSION STUDIES

Measurements of self-diffusion coefficients by means of PFG techniques have evolved to become one of the most important tools in the characterization of liquid surfactant systems. There are essentially two reasons for this, one of which has to do with the measuring technique itself. Thus the PFG approach offers a convenient method of determining self-diffusion coefficients. The technique is outlined in another article in this Encyclopedia (see *Diffusion Measurements by Magnetic Field Gradient Methods*) and has also been described in a number of review articles.^{5,6} Thus we shall not dwell on the technical aspects here. Suffice is to say that the technique requires no isotopic labeling (thus avoiding possible disturbances due to addition of probes); furthermore, it gives component resolved diffusion coefficients with great precision in a minimum of measuring time.

The second reason for its success rests on the fact that the method monitors transport over macroscopic distances (typically of the order of micrometers), and therefore the determined diffusion coefficients reflect aggregate sizes and obstruction effects, yielding information which is easily interpretable in terms of the microstructure of surfactant solutions. The fact that the information is obtained without the need to invoke complicated models, as is the case in the NMR relaxation approach, is particularly important. In this context it should be stressed that the PFG approach measures the self-diffusion rather than the collective diffusion coefficient.

The foundation for the use of NMR to monitor diffusion was laid in 1950 in the seminal paper by Hahn.⁷ Another milestone occurred in the mid-1960s when Stejskal and Tanner demonstrated,⁸ following a suggestion by Douglass and co-workers,⁹ the use of pulsed gradients. Finally, towards the end of the 1960s the method became component resolved when the FT approach was introduced.¹⁰

In its simplest version, the method consists of two equal and rectangular gradient pulses of magnitude g and length δ , sandwiched on either side of the 180° rf pulse in a simple Hahn

echo experiment. For molecules undergoing free (Gaussian) diffusion characterized by a diffusion coefficient of magnitude D , the echo attenuation due to diffusion is given by^{8,11}

$$I(\Delta, \delta, g) = I_0 \exp \left[-\gamma^2 g^2 \delta^2 \left(\Delta - \frac{\delta}{3} \right) D \right] \quad (1)$$

where Δ represents the distance between the two gradient pulses, γ is the magnetogyric ratio of the monitored spin, and I_0 denotes the echo intensity in the absence of any field gradient. By varying either g , δ , or Δ (while at the same time keeping the distance between the two rf pulses constant), D can be determined by fitting equation (1) to the observed intensities.

In the following we use some illustrative examples to show how the PFG approach can be used to obtain information on surfactant solutions.

2.1 Micellar Solutions

2.1.1 The Micellization Process

The PFG method provides a unique way of investigating the process of micellization. The approach is based on the fact that the observed surfactant self-diffusion rates constitute a population weighted average between micellized and monomeric surfactant. This follows since the surfactant lifetime in the micelle is short on the relevant NMR timescale (which is essentially Δ in equation (1), and thus typically around 100 ms). Thus the observed surfactant diffusion coefficient is given by

$$D_{\text{obs}} = p_{\text{mic}} D_{\text{mic}} + (1 - p_{\text{mic}}) D_{\text{free}} \quad (2)$$

where D_{mic} and D_{free} represent the diffusion coefficients of micellized and free surfactant, respectively, and p_{mic} is the fraction of micellized surfactant. Equation (2) can be rearranged to

$$p_{\text{mic}} = \frac{D_{\text{free}} - D_{\text{obs}}}{D_{\text{free}} - D_{\text{mic}}} \quad (3)$$

Clearly, one can obtain the degree of micellization as a function of total surfactant concentration from the concentration dependence of D_{obs} , provided that D_{free} and D_{mic} are known. D_{free} can be obtained from measurements below cmc, while D_{mic} can be obtained from the diffusion coefficient of a hydrophobic probe which is solubilized into the micelles and for which p_{mic} is unity. A suitable probe is hexamethyldisilane (HMDS) which, if it is added in small amounts (on average one probe per micelle is a recommended concentration), seems only negligibly to disturb the micelles (although for some systems it should be used with some care¹²). Once D_{free} and D_{mic} are known, p_{mic} is obtained without the need to invoke any model for the micellization process. For ionic surfactants the same approach can also be used to obtain the degree of counterion association with the micelles, provided that the counterions contain nuclei suitable for PFG work, which is the case for surfactants with organic counterions.

The result of the approach outlined above is shown in Figure 1, in which a textbook example of the micellization

Figure 1 Self-diffusion data for the surfactant ion ($\text{C}_{10}\text{H}_{21}\text{ND}_3^+$) ($\diamond$) and counterion ($\text{CHCl}_2\text{COO}^-$) ($\blacklozenge$) of a cationic surfactant with an organic counterion. Also given are the diffusion coefficients of the micelles ($\square$), as measured by solubilizing a small amount of HMDS into the micelles. By applying the two-site model given by equation (3) one can estimate both the fraction of micellized surfactant and the degree of counterion binding to the micelles from the diffusion coefficients. For instance, at 140 mM total concentration of surfactant $p_{\text{mic}} = 0.8$, while the degree of counterion binding (defined as the ratio of the concentration of micelle associated counterions to the concentration of micellized surfactant cations) is 0.8. (Data from Jansson and Stilbs.¹³)

process is presented. Data are obtained for a system with an organic counterion.¹³ It is difficult to conceive of any other method that would give the same richness of detail concerning the micellization process. Data such as those presented in Figure 1 have been instrumental in testing various models for describing the micellization process. For instance, approaches based on the Poisson–Boltzmann equation have been very successful in rationalizing the process of micellization for ionic surfactants.^{14,15}

2.1.2 Micellar Size and Structure

Questions pertaining to micellar size and structure may be tackled in two ways by means of PFG studies. The first concerns the measurement of self-diffusion of water (or other small molecules) in the system. Any aggregate present obstructs the diffusion of the water and, as the degree of obstruction depends on the volume fraction of the particles present as well as their geometry, information concerning the latter may be obtained. The mathematical description of such obstruction effects was worked out by Jönsson et al.,¹⁶ who presented results for spheres, prolates, and oblates of different sizes and solution volume fractions.

The other approach to investigating micellar structure is based on Einstein's law, in which the (micellar) diffusion coefficient is related to the frictional factor f through

$$D = \frac{k_B T}{f} \quad (4)$$

where k_B is the Boltzmann constant, and T is the absolute temperature.

The friction coefficient depends on the geometry and size of the diffusing particle as well as on the solvent viscosity η . Expressions relating f to the dimensions exist for several

Figure 2 Micelle hydrodynamic radii for two concentrations of $C_{12}H_{25}(OCH_2CH_2)_5OH$ [(●) 2.73 wt%, (○) 0.92 wt% surfactant] and $C_{12}H_{25}(OCH_2CH_2)_8OH$ [(■) 3.06 wt%, (□) 1.02 wt%]. (Data from Nilsson et al.^{18,19})

different geometries, the simplest being that for a sphere of hydrodynamic radius R_H , which is:

$$f = 6\pi\eta R_H \quad (5)$$

For cases where the geometry is not known, one often uses equation (5) and computes a hydrodynamic radius, on the assumption that the diffusing species is a sphere. An example of this approach is shown in Figure 2, which gives the hydrodynamic radii for micelles formed by nonionic surfactants of the oligo(ethylene oxide) type as a function of temperature. Questions pertaining to the aggregate growth as a function of temperature and concentration in these systems have been the subject of rather lively discussion over the years.¹⁷ Clearly, data such as those presented in Figure 2 are important in this context.^{18–20}

Although the method outlined above is certainly useful, one should be aware of the limitations inherent in the approach. First, equations (4) and (5) assume infinite dilution. As micelles are self-assembled units, one must be aware of the fact that dilution may change their properties. At higher concentrations particle–particle obstruction effects become important, and these must be taken into account.^{21,22}

2.2 Microemulsions

Microemulsions are defined as thermodynamically stable systems containing an oleic solvent (in most basic research a simple hydrocarbon is used), a hydrophilic solvent (most often water or brine), and a surfactant (which can be a combination of several amphiphilic molecules). For weakly amphiphilic molecules the system is molecularly dispersed; this will not be discussed here.

Of particular interest are systems in which small amounts of surfactant may bring equal volumes of oil and water into solution. This can be achieved with less than 1% surfactant, and such systems are usually termed ‘balanced’.²³ In many of these systems one may vary the oil to water volume ratio extensively without ever leaving the one-phase microemulsion

Figure 3 Phase diagram of an alkylpolyglucoside/cosurfactant/water/cyclohexane system at 25 °C with a total surfactant + cosurfactant concentration of 4 wt%. The number of phases present in the various regions of the phase diagram is indicated (for example, the one-phase microemulsion is denoted by 1Φ). (Reproduced with permission from Fukuda et al.²⁴)

region. This is achieved by varying some parameter. Such a parameter is constituted by the temperature in the case of nonionic surfactants of the C_xE_y type, the salinity of the water for ionic surfactants, and the cosurfactant/surfactant ratio in a mixed surfactant system. An example of such behavior is shown in Figure 3, where a recently compiled phase diagram for an alkylpolyglucoside surfactant is displayed. In this case it is the proportion of the cosurfactant (which is a branched alkyl glycerol monoether) in the surfactant mixture which was varied.²⁴

It is a considerable challenge to model such a system, and a prerequisite for such an endeavor is the availability of structural information. It is perhaps in this context that the PFG approach has achieved its most spectacular successes, not least due to the fact that very few other methods can yield such information for microemulsions. How then do we infer structural information from self-diffusion coefficients which are dynamic quantities? The basis of the approach is the fact that the mean distance traveled by the molecules is of the order of $\sqrt{\Delta D}$, which quantity is of the order of micrometers for low molecular weight liquids. Thus any obstruction effects or confinement to droplets of colloidal dimensions affects the diffusion coefficient.

Broadly speaking, one can differentiate between a microstructure of closed particles, whether they are normal (enclosing the oil component) or reversed (enclosing the water), and a microstructure which is bicontinuous. The latter term is often used without being properly defined. We shall take it to imply that a large fraction of both the oil and water molecules exists in domains which span macroscopic distances in three dimensions.

For the case of discrete particles, the continuous phase displays a diffusion behavior similar to that of the neat liquid. There will be solvation effects, i.e. some of the continuous solvent may be associated with the surfactant and, as a consequence, will have an altered diffusional behavior. However, for low surfactant concentration this effect is negligible. Thus any reduction in the reduced diffusion coefficient for the continuous solvent (in PFG studies of microemulsions one preferably reports the reduced diffusion

coefficient, defined as D/D_0 , where D_0 is the bulk diffusion coefficient of the neat liquid at the same temperature) can be attributed to particle obstruction effects (see above). If both the dispersed phase and the surfactant have negligible solubility in the continuous phase, their diffusion is given by the particle diffusion, and so both have the same diffusion coefficient, the value of which can be used to estimate the size of the diffusion particle from equation (4), while the concentration dependence of the diffusion coefficient can be used to infer information about the interaggregate interactions.²²

Turning to the bicontinuous case we note first that both the water and the oil component diffuse rapidly. Careful PFG work using mixtures of oil has revealed that the diffusion process of the oil component is very similar to the diffusion in neat oil.^{25,26} The same holds for the water component.²⁷ This is an important observation, which implies that any reduction in the reduced diffusion coefficient can be attributed to the obstruction effects due to the presence of the surfactant film. Effects such as exchange between droplets and fusion–fission processes cannot explain the rapid oil and water diffusion. Any structural model of microemulsions must not be at variance with this statement. It should be emphasized that, at present, the PFG method is the only way in which bicontinuity may be proved or disproved. Two-dimensional images cannot prove bicontinuity, since it cannot exist in two dimensions.²⁸

Let us now investigate whether the diffusion data for the system in Figure 3 is in line with this reasoning. Figure 4 shows the reduced diffusion coefficients for the water and oil components in the system shown in Figure 3 as a function of the volume fraction of hydrocarbon in the solvent mixture (Φ_{oil}). The data in Figure 4 are typical for microemulsions where the oil content can be varied continuously from no oil to pure oil. Thus the water and oil component diffusion changes continuously from rapid to slow as the fraction of each component is decreased, and the plots of the reduced diffusion coefficients versus the volume fraction of oil in the solvent mixture show a rather characteristic ‘sigmoidal’ curve for both components. At equal volume fractions of oil and water the curves intersect, and the value of both reduced diffusion

Figure 4 The relative self-diffusion coefficients of water ($\diamond$) and hydrocarbon ($\blacklozenge$) as a function of the volume fraction, Φ_{oil} of hydrocarbon in the solvent mixture, for microemulsions formed in the alkylpolyglucoside/cosurfactant/water/cyclohexane system, the phase diagram of which is shown in Figure 3. (Data from Fukuda et al.²⁴)

coefficients is around 0.6 at the point of intersection. In line with the discussion above, this points to discrete particles at low and high values of Φ_{oil} and a bicontinuous structure in between. Based on the information inherent in PFG data such as those presented in Figure 4, how should we picture the bicontinuous microemulsions?

A most fruitful way of looking at these phases is due to Scriven²⁹ who proposed the idea that the structure could be described as a melted liquid crystalline cubic phase, for which the structure is known on account of the scattering studies that can be performed on these systems [cubic phases come in two varieties (discrete and bicontinuous); Scriven had the latter class in mind]. These are formed by two interwoven subvolumes of the same material (polar or nonpolar), which are separated by a film of the opposite material. This dividing film is described as a ‘minimal surface’, having zero mean curvature.

Now, allow this structure to melt, so that the long range order is lost, but locally the structure is retained. When the material on both sides is equal, L_3 phases or bicontinuous micellar solutions (see below) are formed, and the dividing film is a bilayer, while for the case where the two subvolumes are not equal, microemulsions are formed. For this case the dividing film is a monolayer, with a curvature towards the oil or water depending on the volume fraction of the two components.

In an important contribution, Anderson and Wennerström³⁰ have computed the obstruction effect for components in the subvolumes and for components diffusing along the dividing surface. Indeed, these workers found that the reduced diffusion coefficient for a bicontinuous microemulsion with roughly equal oil and water volume fractions is around 0.6, giving further credence to Scriven’s suggestion.

Finally, we note that, when measurements are possible, the value of the surfactant self-diffusion coefficient often displays a maximum with respect to changes in the solvent composition at equal oil and water volume fractions. This observation is more difficult to interpret in terms of a particular microstructure, owing to the difficulties of finding a suitable reference value for the lateral diffusion coefficient for the surfactant along the surfactant film, but it does indicate that the surfactant is diffusing over surfaces that extend over several micrometers with only minor disturbances for diffusions. Consider, for example, the case of a sodium dodecyl sulfate (SDS) microemulsion,³¹ where D for the surfactant was found to be $1.5 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ at 27°C , a value which is in good agreement with the values found for lateral diffusion of SDS over a micellar surface of spherical³² ($D = 1.0 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ at 30°C) and cylindrical³³ ($D = 1.69 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ at 30°C) geometry, where the diffusion is indeed unhindered.

2.3 L_3 -Phases and Bicontinuous Micellar Solutions

The properties of L_3 phases and bicontinuous micellar solutions have been discussed extensively, and they constitute an illustrative example of the power of the PFG method in unravelling solution structure. Both types of solution have a connected structure, and again a fruitful starting point is the (known) structure of the cubic phases. If a cubic phase is diluted with the material of the subvolumes, an L_3 phase

Figure 5 Variation in the reduced water diffusion coefficient with the volume fraction of surfactant in the L_3 ($\diamond$) and cubic ($\blacklozenge$) phases formed in the AOT/water/NaCl system. (Data from Balinov et al.³⁴)

(sometimes known as L^* or ‘sponge’ phase) is formed, while dilution with the material of the dividing film gives rise to a bicontinuous micellar solution. Let us consider the L_3 phase formed in the sodium bis(2-ethylhexyl)sulfosuccinate (AOT)/brine system. In this system, the L_3 phase is in equilibrium with a bicontinuous cubic phase via a two-phase region.³⁴ Figure 5 gives the reduced diffusion coefficients for the water as a function of the surfactant volume fraction Φ_s in both the L_3 and the cubic phase.

There are two noteworthy features of the data shown in Figure 5. First, there is a continuous change in D/D_0 with Φ_s over the two-phase area between the L_3 and cubic phases. Secondly, at high dilution, a limiting value of D/D_0 of around 0.65 is obtained. The first observation indicates that the microstructures in the two phases are similar, since the translational diffusion of water reflects the microstructure of the solution. The second point can be used to infer information about the microstructure in a slightly more rigorous way. Consider a structure of discrete particles. According to the obstruction factors derived by Jönsson et al.,¹⁶ the only geometry that would give rise to a reduction in D/D_0 from 1 to 0.65 would be large disks with an axial ratio in excess of 100:1. This is not in agreement with the surfactant diffusion, which, for the case of disks, implies an axial ratio of 12:1. Thus we are forced to think of alternative microstructures. Following the suggestion inherent in the first feature of the data in Figure 5, i.e. that the microstructures are similar in the L_3 and cubic phases, let us consider the case of a bilayer continuous structure. As noted above, this case has been treated by Anderson and Wennerström,³⁰ who obtained a value of 0.65 for the reduced diffusion coefficient for the solvent diffusion at low volume fraction of bilayer (in fact, for an infinitely thin multiply connected bilayer, the limiting value is $\frac{2}{3}$, on account of the dimensionality of the bilayer). Moreover, by analyzing the dependence of D/D_0 on Φ_s , information can be obtained regarding the coordination number of the obstructing surface.³⁵

The analysis of the bicontinuous micellar solution structure as based on PFG data follows the same approach as the one described above. Readers interested in this particular micellar solution are referred to the paper by Monduzzi et al.³⁶

Figure 6 A ^1H NMR FT PFG experiment at 100MHz on the solubilization of neopentanol into dodecyltrimethylammonium chloride micelles (solvent D_2O). The degree of solubilization is obtained directly from the evaluated D values for neopentanol in the micellar solution and in an aqueous solution [see equation (3)]. The value for the micellar diffusion coefficient, which is obtained from a small amount of solubilized tetramethylsilane (TMS), is also needed. The gradient current was varied linearly between successive spectra, which were obtained at fixed intergradient (Δ) and rf pulse (τ) intervals

2.4 Solubilization

As a final illustration of the power of the PFG approach, we consider the topic of solubilization. By ‘solubilization’ we mean the incorporation of molecules which are not water soluble into the micellar subvolume of a micellar solution. An important question pertaining to the phenomenon of solubilization concerns the degree of partitioning between the micelles and the water. This question is related to that pertaining to the micellization process (see above), and the same approach used to study that process can be used to investigate solubilization. Thus the degree of solubilization p can be determined by measuring the diffusion coefficient of the solubilize in the absence and presence of micelles, and determining the diffusion coefficient for the micelle (using the approach outlined above) by using equation (3). From the volume or weight fraction of the micellar subvolume and the value of p , one can then determine the desired partition coefficient. A typical PFG solubilization experiment is shown in Figure 6.³⁷

There are several advantages of the PFG approach as compared with other techniques for studying solubilization. The experiment is simple as well as selective. The latter point is particularly important, as one can determine the solubilization of several different solubilizes simultaneously, and each individual value of p can be determined. The presence of impurities is normally not a problem. The quantity p is well defined and easily interpreted. Finally, by measuring the surfactant diffusion one can independently check whether the micelles as such are altered by the presence of solubilizes. Clearly, the whole topic of solubilization becomes somewhat less meaningful if one does not have control over the state of the micelles.

3 RELAXATION STUDIES

NMR relaxation has proven to be a useful experimental technique for studying surfactant aggregation in liquid solutions

and liquid crystals.^{20,38–40} The experiment yields information on the local dynamics and conformational state of the surfactant hydrocarbon chain and has demonstrated the liquid-like interior of surfactant micelles. However, the main purpose of NMR relaxation studies of isotropic micellar solutions and microemulsions has been to study properties such as the aggregate size.

The reorientation dynamics of aggregated surfactant molecules, which are discussed in more detail below, are characterized by the fact that they locally have a preferred orientation, forming essentially a monomolecular film of oriented molecules. Locally, surfactant molecules undergo rapid internal motions, such as *trans*–*gauche* isomerizations in the hydrocarbon chain. These motions are, due to the preferred orientation, slightly anisotropic. The situation can be pictured as the polar headgroups being anchored at the polar–apolar interface, leaving room for dangling motions of the hydrocarbon chains, with certain restrictions on the number of conformations due to packing constraints in the film. In isotropic solutions the residual interaction or anisotropy is further averaged by the thermal tumbling of the aggregates in combination with the diffusion of surfactant molecules within the curved surfactant film.

NMR spectra from surfactants in micellar solutions and microemulsions are generally in the motional narrowing regime, and the spin dynamics are characterized by well-defined relaxation times. Exceptions can be found in solutions of very long ($>10^2$ nm) wormlike cylindrical micelles where the large size in connection with steric overlap gives rise to a very slow (about 10^{-4} s) aggregate reorientation.^{41,42} On the other hand, the dynamics are typically outside the extreme narrowing regime, and one often observes $R_2 \gg R_1$, where R_1 and R_2 are the longitudinal and transverse relaxation rates, respectively. Micellar aggregates reorient on a timescale of 10^{-9} s or slower. Thus, at conventional magnetic field strengths, the essential information on the surfactant aggregates is stored in the transverse relaxation rate R_2 .

A hydrocarbon, typically an alkyl chain of 12–16 carbon atoms, constitutes the major part of surfactant molecules, offering ^1H and ^{13}C nuclei for NMR studies. Being spin- $\frac{1}{2}$ nuclei, the relaxation is mainly due to dipole–dipole interactions (although chemical shift anisotropy and scalar interaction can sometimes be important in the case of ^{13}C). The easy access and the relatively high sensitivity (which was particularly important in early CW NMR studies) has made ^1H NMR (in particular bandwidth measurements) studies particularly popular. Micellar growth can easily be studied qualitatively by monitoring the bandwidth of aliphatic ($-\text{CH}_2-$) protons in the spectrum. Quantitative analysis is, however, complicated by the coupling of the various protons having locally different motional characteristics along the alkyl chain. In an alkyl chain of, say, 16 carbon atoms, the protons constitute a coupled spin system of approximately 2^{16} spin states, which can have a broad spectrum of transition rates, resulting in significant deviations from a Lorentzian bandshape of the CH_2 resonance.^{41,43} This complexity can, however, be turned into an advantage in that it allows for a continuum description of the transition rate spectrum. The ^1H bandshape problem was analyzed by Wennerström et al.^{41,43} within the two-step formalism (see below), and quantitative ^1H bandshape analyses have been performed in systems of

large, slowly reorienting micelles.^{41,42} In contrast to the non-Lorentzian band shape, one often observes an exponential longitudinal relaxation due to rapid internal equilibration of the spin system (spin diffusion), and the frequency dependence of R_1 has been measured by using field cycling techniques.^{44,45}

In an alkyl chain, the ^{13}C nuclei are relaxed by the fluctuating dipole–dipole coupling to the directly bound protons. The various carbon atoms along the chain are normally resolved. Usually, one applies broadband proton decoupling, resulting in exponential longitudinal relaxation of the individual ^{13}C magnetizations, and it is possible to determine R_1 and the nuclear Overhauser enhancement of the different methylene segments. On the other hand, it is difficult to measure R_2 on ^{13}C . Therefore, ^{13}C is mainly useful for studying local chain dynamics and segmental order, since the aggregate dynamics occur on timescales which are normally long relative to the inverse ^{13}C resonance frequency.

Certain surfactants carry phosphate or ammonium polar headgroups, offering ^{31}P and ^{14}N nuclei, respectively, for relaxation studies. The phosphate ^{31}P ($I = \frac{1}{2}$) has a relatively large chemical shift anisotropy which is strongly dependent on the pH (degree of protonation), complicating the analysis of relaxation data. ^{14}N is a $I = 1$ nucleus and its relaxation is dominated by the strong quadrupolar interaction. Except for the case of quaternary ammonium groups, the magnitude and asymmetry of the quadrupolar coupling is also pH dependent, and special care has to be taken.

The most suitable nucleus for relaxation studies of surfactant systems is ^2H , which can be incorporated synthetically into the hydrocarbon chain of the surfactant molecule. Normally, one selectively labels a single methylene segment, typically one adjacent to the polar headgroup, in order to avoid resonance overlap in the spectrum. ^2H is a $I = 1$ nucleus, and the dominating interaction governing the relaxation is the strong quadrupolar interaction. For aliphatic ($\text{C}-^2\text{H}$) deuterons, the analysis is further simplified by the fact that the electric field gradient tensor has essentially cylindrical symmetry around the $\text{C}-^2\text{H}$ bond direction, resulting in a vanishing asymmetry parameter. The ease with which both R_1 and R_2 can be accurately measured, the relatively simple interaction Hamiltonian, and the sufficiently high sensitivity allowing measurements to be made at low resonance frequencies (down to 2 MHz using variable field electromagnets), give ^2H NMR relaxation a particularly important role among the different experimental tools available for studying surfactant systems.

The utility of the NMR technique as an experimental tool in surfactant science can be made apparent by comparing the strengths and weaknesses of the NMR relaxation technique with those of other experimental techniques. In comparison with other experimental methods used in studying, for example, micellar size, the NMR relaxation technique has two major advantages, both of which are associated with the fact that it is reorientational motions which are measured. One is that the relaxation, i.e. R_2 , is sensitive to small variations in micellar size. Consider, for example, a sphere for which the rotational correlation time is proportional to the cube of the radius. This can be compared with the translational self-diffusion coefficient which varies linearly with the radius. The second, and perhaps most important advantage is the fact that the rotational diffusion of particles in solution is essentially independent of interparticle interactions (electrostatic and hydrodynamic). This is in contrast to most

other techniques (such as viscosity, collective and self-diffusion, scattered light intensity, etc.) available for studying surfactant systems or colloidal systems in general. In this latter respect, NMR relaxation experiments are comparable with form factor determinations with small angle X-ray or neutron scattering experiments. A weakness of the NMR relaxation approach to aggregate size determinations, compared with form factor determinations, would be the difficulties of absolute calibration, since the transformation from information on dynamics to information on structure must be performed by means of a motional model.

3.1 Timescale Separation: The Two-Step Model

In this section we discuss a motional model^{46–48} of aggregated surfactant molecules, which involves a timescale separation of fast local and slow global motions. This model has been applied extensively to, and shown to rationalize, NMR relaxation data from aggregated surfactant systems. We discuss the model in connection with ^2H relaxation experiments, since the most extensive experimental studies have been performed on ^2H -labeled surfactants. We begin by recalling that the longitudinal (R_1) and transverse (R_2) relaxation rates of an $I = 1$ nucleus, due to the quadrupolar interaction in an isotropic solution, are given by⁴⁹

$$R_1 = \frac{3\pi^2}{40} \chi^2 [2j(\omega_0) + 8j(2\omega_0)] \quad (6a)$$

$$R_2 = \frac{3\pi^2}{40} \chi^2 [3j(0) + 5j(\omega_0) + 2j(2\omega_0)] \quad (6b)$$

where χ is the quadrupolar coupling constant, and $j(\omega_0)$ is the reduced spectral density function evaluated at the Larmor frequency ω_0 .

Based on existing knowledge of surfactant aggregate structures, Wennerström and co-workers^{46–48} suggested that the reorientational motion of surfactant molecules can be divided into: (i) fast local motions (equilibration of internal modes), which are slightly anisotropic due to the preferred orientation of the surfactant molecules; and (ii) slow isotropic motions, associated with the aggregate tumbling and the lateral diffusion of surfactant molecules within the aggregates. If these two motions occur on significantly different timescales, the fast motions generate a well-defined residual anisotropy to be averaged by the slow motions, and the spectral density can be written as a weighted sum of the fast and the slow components

$$j(\omega_0) = (1 - S^2)j_f(\omega_0) + S^2j_s(\omega_0) \quad (7)$$

where $j_f(\omega_0)$ and $j_s(\omega_0)$ are the reduced spectral density functions describing the fast and slow motions, respectively. The parameter S is often referred to as an ‘order parameter’ and is given by the average

$$S = \frac{1}{2} \langle 3 \cos \theta_{\text{MD}} - 1 \rangle_f \quad (8)$$

where θ_{MD} is the angle between the axis of the maximum component of the electric field gradient tensor and the director axis.

The situation for the case of a ^2H -labeled methylene segment of a surfactant molecule residing in a micelle is

Figure 7 Schematic illustration of the various coordinate frames considered within the two-step model, for the case of a specifically ^2H -labeled methylene segment in the surfactant hydrocarbon chain. The laboratory frame (L) is set by the direction of the external magnetic field, where Z_L is the field direction. In this frame the nuclear quadrupolar moment tensor is diagonal. The director frame (D) is associated with the micellar aggregate, where Z_D specifies the micellar surface normal. It is assumed that the fast local dynamics occur with an essentially cylindrical symmetry around Z_D . The molecular frame (M) corresponds to the principal axis of the electric field gradient tensor. For the case of a methylene segment, Z_M specifies the maximum component of the field gradient tensor, which is also cylindrically symmetric around Z_M

illustrated in Figure 7. The director axis Z_D corresponds to the micellar surface normal. The field gradient tensor is cylindrically symmetric around the C–D bond axis, with the maximum component in the bond axis direction Z_M .

In equation (7) it is also assumed that the fast motions have an effective three-fold or higher symmetry around the director. For most situations, however, one may expect an effectively cylindrical symmetry. For lower than three-fold symmetry, equation (7) must be extended to include a second-order parameter, describing the residual order in the plane perpendicular to the director. A similar extension is also necessary when the electric field gradient has a nonvanishing asymmetry parameter (for an extensive discussion, see Halle and Wennerström⁴⁸).

3.2 Frequency Dependent Relaxation Studies of Small Spherical Micelles

The fast motions, described by the spectral density function $j_f(\omega_0)$, are expected to occur on a similar timescale ($\tau_f \approx 10^{-11}$ s) as in the corresponding liquid alkane. Thus this motion is in extreme narrowing ($\tau_f \ll 1/\omega_0$) in the accessible frequency range, and we may assume that $j_f(2\omega_0) \approx j_f(\omega_0) \approx j_f(0) = 2\tau_f$, where τ_f should be considered as an effective correlation time, representing the integral over a nonexponential correlation function.

The slow motion is a combination of micelle tumbling and the lateral diffusion of surfactant molecules within the surfactant film. For spherical aggregates, this motion is described by a Lorentzian spectral density function:

$$j_s(\omega_0) = \frac{2\tau_s}{1 + (\omega_0\tau_s)^2} \quad (9)$$

where τ_s is the correlation time. The tumbling and the lateral diffusion are expected to be statistically independent, in which case the correlation function can be factorized:

$$G_s = G_t G_d = e^{-t/\tau_t} e^{-t/\tau_d} = e^{-t/\tau_s} \quad (10)$$

where subscripts t and d refer to tumbling and lateral diffusion, respectively, and the slow correlation time can be written as

$$\frac{1}{\tau_s} = \frac{1}{\tau_t} + \frac{1}{\tau_d} \quad (11)$$

The correlation time associated with the tumbling of a sphere of radius R is given by

$$\tau_t = \frac{4\pi\eta R^3}{3k_B T} \quad (12)$$

where η represents the solvent viscosity, and $k_B T$ is the thermal energy. The effect of lateral diffusion can be described in terms of diffusion on the surface of a sphere of radius R . In this case, the correlation time can be written as

$$\tau_d = \frac{R^2}{6D_{\text{lat}}} \quad (13)$$

where D_{lat} is the lateral diffusion coefficient.

With the assumptions of (i) extreme narrowing conditions for the fast motions and (ii) a Lorentzian spectral density function of the slow motion, the expressions for the relaxation rates become, with equation (7)

$$R_1 = \frac{3\pi^2}{40} \chi^2 \left\{ (1 - S^2)20\tau_f + S^2 \times \left[\frac{4\tau_s}{1 + (\omega_0\tau_s)^2} + \frac{16\tau_s}{1 + (2\omega_0\tau_s)^2} \right] \right\} \quad (14a)$$

$$R_2 = \frac{3\pi^2}{40} \chi^2 \left\{ (1 - S^2)20\tau_f + S^2 \times \left[6\tau_s + \frac{10\tau_s}{1 + (\omega_0\tau_s)^2} + \frac{4\tau_s}{1 + (2\omega_0\tau_s)^2} \right] \right\} \quad (14b)$$

Equations (14a) and (14b) have been applied in a large number of ^2H NMR relaxation studies of micellar systems. It turns out that frequency dependent relaxation studies are particularly useful for studying small spherical micelles, which typically have a radius of about 2 nm. Using the water viscosity and equation (12) we obtain $\tau_t \approx 7$ ns at room temperature (25 °C). Including the effect of lateral diffusion, a typical value of the slow correlation time is $\tau_s \approx 5$ ns. Thus, the relaxation dispersion from the slow motion occurs around ν_0

Figure 8 The variation in R_1 and R_2 with the Larmor frequency for ^2H nuclei bound to the α -methylene segment of the surfactant hexadecyltrimethylammonium chloride. The sample was an aqueous micellar solution containing 13 wt% of the surfactant. Experiments were performed at 27 °C. (Data from Söderman et al.⁵¹)

$\approx (2\pi\tau_s)^{-1} \approx 30$ MHz, which is well within the accessible Larmor frequency range for ^2H .

To investigate the applicability of the motional model, Söderman and co-workers^{50,51} studied aqueous micellar systems of alkyltrimethylammonium chloride surfactants of two different alkyl chain lengths: dodecyl and hexadecyl chains. The alkyl chains were ^2H labeled in the α -methylene segment, adjacent to the ammonium polar headgroup, and the relaxation rates R_1 and R_2 were measured in the Larmor frequency range 2–55 MHz, in order to cover the dispersion of the slow motion. The lower frequencies were obtained by using a variable field electromagnet. The results⁵¹ obtained for the hexadecyltrimethylammonium chloride micelles (concentration 13 wt%) are shown in Figure 8. The solid lines are best fits of equations (14a) and (14b) to the whole data set, using τ_f , τ_s , and S as adjustable parameters. As can be seen from Figure 8, the data are well described by a Lorentzian spectral density function superimposed on a constant offset in the investigated frequency range, thus supporting the assumption of timescale separation. The fit yielded $\tau_f = 42 \pm 1$ ps, $\tau_s = 7.6 \pm 0.4$ ns, and $S = 0.186 \pm 0.003$, where the uncertainties correspond to an approximately 80% confidence interval taking only random errors into account, and a value of $\chi = 167$ kHz was used for the quadrupolar coupling constant.

The slow correlation time was interpreted in terms of equations (11)–(13), which contain two unknown parameters, R and D_{lat} . However, D_{lat} can be measured in phases of extended surfactant films, such as bicontinuous cubic phases, and R is expected to be close to the overall length of the surfactant molecule. Using $D_{\text{lat}} \approx 1 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$, as measured in a bicontinuous cubic phase of the similar surfactant hexadecylammonium fluoride, and the radius $R = 2.37$ nm, a slow correlation time of approximately 10 ns was calculated from equations (11)–(13), which is in reasonable agreement with the experimentally determined value.

The applicability of the two-step model receives further support when comparing the S value obtained from the fit to the relaxation dispersion with that measured from quadrupolar

splittings in liquid crystalline phases formed at higher surfactant concentrations. In the liquid crystalline phases, extended surfactant aggregates are 'locked' in a crystalline array. Two very common structures are the lamellar phase, where surfactant bilayers are stacked with one-dimensional order, and the hexagonal phase, where cylindrical aggregates are packed on a two-dimensional hexagonal lattice. In these phases one has effectively frozen the slow motion, and the nuclei experience a static quadrupolar Hamiltonian $\langle \hat{H}_Q \rangle_f$ in addition to the Zeeman term, where the average is taken over the fast local motions. This results in a quadrupolar splitting of magnitude⁴⁶

$$\Delta_{\text{lam}} = \frac{3}{4} \chi |S| \quad (15)$$

in the lamellar phase with planar films. In the hexagonal phase, the rapid surfactant diffusion around the cylinder axis results in an additional averaging of the interaction by a factor of 2 and the splitting is given by

$$\Delta_{\text{hex}} = \frac{3}{8} \chi |S| \quad (16)$$

One may expect that the local motions, and hence the S value, should be similar in the liquid crystalline surfactant aggregates and the micelles in the dilute solution phase. This is in fact found to be the case. As mentioned above, the S value obtained from the fit to the relaxation dispersion (Figure 8) was found to be $S = 0.186$. A very similar value (0.192) was measured in the hexagonal phase at higher concentrations.⁵¹

3.3 Larger Aggregates: Use of the Zero Frequency Spectral Density

The small spherical micelles ($R \approx 2$ nm) can be seen as a limiting case, and in general surfactant aggregates have much larger extensions. When the size of the aggregates increases, τ_s increases as well, and the relevant relaxation dispersion moves out of the accessible frequency window. In some extreme cases, for example with long, entangled wormlike micelles, the dynamics may even move out of motional narrowing, showing slow motion effects in the NMR spectrum.⁴² However, for most micellar and microemulsion systems, the motional narrowing condition applies. In these cases, valuable information may be obtained by measuring R_1 and R_2 for ^2H -labeled surfactants at a single Larmor frequency. For larger aggregates, the relevant information on the aggregate size is contained in the zero frequency spectral density only. Assuming that the fast motions are in extreme narrowing, in which case they contribute to a constant offset of both R_1 and R_2 , it is useful to consider the difference $\Delta R = R_2 - R_1$ which then depends only on the slow motions. For the case of very slow motions, we also have $j_s(0) \gg j_s(\omega_0) \approx j_s(2\omega_0)$, and ΔR can be approximated by

$$\Delta R = \frac{9\pi^2}{40} (\chi S)^2 j_s(0) \quad (17)$$

This expression has been used to study variations in the shape of surfactant aggregates in different microemulsion

systems.^{52,53} Here, the micellar aggregates are swollen by the addition of a third component (normal micelles in aqueous solution are swollen by oil; reverse micelles in oil are swollen by water), where spherical aggregates can have radii of the order of 10 nm. Quantitative applications of equation (17) require reliable determinations of S from adjacent liquid crystalline phases. Furthermore, they require assumptions concerning the aggregate shape, and a knowledge of D_{lat} , to determine, for example, an aggregate radius of spherical aggregates. So, obviously, there are some uncertainties involved concerning the 'absolute calibration' of the method.

The situation can, however, be optimized by noting that the aggregates are formed under the constraint of a constant average interfacial area/enclosed volume ratio, set by the surfactant/internal component concentration ratio. With this constraint, the minimum aggregate size corresponds to a spherical shape. Due to the entropy of mixing, spherical aggregates, representing the minimum aggregate size, will always be stable at high dilutions, where the experiment can be calibrated. In many cases, D_{lat} is also known quite accurately from the various bicontinuous phases of the different systems.

Deviations from spherical shape can be modeled as a growth into prolate or oblate shapes. The interfacial area/enclosed volume constraint implies a constraint on the possible values of the two semiaxes describing the particle size. Halle⁵⁴ has calculated the correlation functions for the combined particle tumbling and surface diffusion of prolate and oblate particles. His results have been applied to, for example, microemulsion systems,^{52,53} focusing on the ratio $j_{s,\text{pr}}(0)/j_{s,\text{sph}}(0)$, where the subscripts pr and sph refer to prolate and spherical particles, respectively. For a given interfacial area/enclosed volume ratio, which specifies the radius R of the sphere, $j_{s,\text{pr}}(0)/j_{s,\text{sph}}(0)$ is a function of the prolate axial ratio D_{lat} , and R . Knowing D_{lat} and R from other experiments it is possible to determine the aggregate axial ratio from the relaxation experiment.

As mentioned above, the strength of the NMR relaxation technique in comparison to other (e.g. scattering) techniques for studying micelles and microemulsions is related to the fact that rotational dynamics are monitored. This has the advantages that (i) the dynamics are sensitive to small size variations, and (ii) the dynamics are essentially independent of interactions. In an extensive study of a three-component microemulsion system composed of the nonionic surfactant pentaethyleneoxide dodecyl ether, water, and decane, oil swollen micelles dispersed in water were investigated over a large concentration range.⁵²

With a nonionic surfactant, spherical aggregates are formed at lower temperatures, while the aggregates grow in size with increasing temperature.¹⁷ Figure 9 shows the variation of ΔR with temperature for two compositions, $\Phi = 0.12$ and 0.23, in the microemulsion phase.⁵² Here, $\Phi = \Phi_s + \Phi_o$ is the total volume fraction of surfactant (Φ_s) and oil (Φ_o), and the ratio $\Phi_s/\Phi_o = 0.815$ was kept constant.

The value of ΔR decreases when the temperature is decreased in the microemulsion phase and levels off at lower temperatures at a minimum value ΔR_{min} , when the aggregates have reached the limiting spherical shape, corresponding to the minimum size. Note that the minimum ΔR value is the same for the two concentrations, as is expected because the radius, dictated by Φ_s/Φ_o , should be the same. By considering

Figure 9 Variation in ${}^2\text{H}$ $\Delta R = R_2 - R_1$ with temperature of the ${}^2\text{H}$ -labeled nonionic surfactant pentaethyleneoxide dodecyl ether $[\text{CH}_3(\text{CH}_2)_{10}\text{C}^2\text{H}_2(\text{OCH}_2\text{CH}_2)_5\text{OH}]$ in a ternary system with water and decane. The ratio Φ_s/Φ_o is 0.815, where Φ_s and Φ_o are the surfactant and oil volume fractions, respectively. The concentrations are $\Phi = \Phi_s + \Phi_o = 0.12$ and 0.23 , respectively. (Data from Leaver et al.⁵²)

the reduced ΔR value, $\Delta R/\Delta R_{\min} = j_{s,\text{pr}}(0)/j_{s,\text{sph}}(0)$, it was possible to calculate the increase in the axial ratio of the aggregates with increasing temperature, assuming a growth into prolate aggregates. The variation in the axial ratio obtained is shown in Figure 10.

Very large micelles may also form in binary surfactant systems. These are long wormlike micelles which become entangled at higher concentrations, giving rise to rheological properties similar to those in polymer solutions. Such systems have been examined by means of ${}^1\text{H}$ bandshape analysis.^{41,42} The protons of the surfactant hydrocarbon chain form a very large dipolar coupled spin system, with essentially a continuum distribution of transverse relaxation rates. The distribution of relaxation rates is related to the distribution of order parameters,⁴³ which can be obtained from analyzing the bandshape in the liquid crystalline (lamellar or hexagonal)

Figure 10 Variation in the micellar axial ratio with temperature, assuming a monodisperse prolate growth, as deduced from the relaxation data in Figure 9 by using the correlation function due to Halle,⁵⁴ for the combined motion of aggregate tumbling and surface diffusion

phases, where the bandshape is associated with a continuum distribution of residual dipolar splittings.⁵⁵

Slow motions have also been studied by measuring the differential line broadening (DLB) of proton J coupled ${}^{13}\text{C}$ nuclei.⁵⁶ Here the difference in bandwidth of the different resonances in a ${}^{13}\text{C}$ multiplet can be attributed to the interplay between the dipole–dipole and chemical shift anisotropy relaxation mechanisms, and by analyzing the difference, information on the slow motion may be obtained.

3.4 Relaxation Measurements on Water and Counterion Nuclei

Relaxation measurements on water and counterion nuclei may also give information about the surfactant aggregate size and shape. Such measurements may be particularly useful in reverse micellar systems, where water and surfactant counterions are contained in small water pools covered by a surfactant monolayer. In a ${}^{23}\text{Na}$ ($I = \frac{3}{2}$) spin relaxation study of a reverse micellar system, the presence of slow motions was found to result in a biexponential free induction decay (FID).⁵⁷ Using the two transverse relaxation rates and an effective longitudinal relaxation rate, it was possible to determine all three spectral density values: $j(0)$, $j(\omega_0)$, and $j(2\omega_0)$. From the fit of the imaginary part of the FID it was also possible to determine the second-order quadrupolar dynamic shift, allowing for an additional test of the motional model invoked in the interpretation of the data.

An interesting application of water nuclei relaxation in microemulsions concerns the so-called ‘nuclear spin quenching’ studied by Carlström and Halle.⁵⁸ Here, the effect of chemical exchange of water protons, mediated by the presence of prototropic ions, H_3O^+ and OH^- , on the ${}^{17}\text{O}$ bandshape in a reverse micellar system was investigated. By careful analysis of the ${}^{17}\text{O}$ bandshape, information on the water exchange kinetics between droplets as well as the droplet size was obtained.

3.5 Surfactant Hydrocarbon Chain Conformations in Micelles

The early findings of narrow ${}^1\text{H}$ bands from the surfactant hydrocarbon chains in small spherical micelles revealed that the micellar interior is in a liquid-like state. Magnetic field dependent ${}^{13}\text{C}$ R_1 relaxation experiments confirmed those ideas, and a segmental order parameter profile, similar to that obtained from ${}^2\text{H}$ quadrupolar splittings in lipid bilayer systems, was obtained within the two-step formalism.⁵⁹ By studying the dynamics of a symmetric probe molecule solubilized in micelles, it was concluded that the micellar interior was characterized by an effective viscosity similar to that of the neat hydrocarbon.⁶⁰

Chachaty and co-workers^{40,61} have studied the enhanced relaxation rate due to the presence of paramagnetic counterions. The multivalent paramagnetic counterion is expected to be selectively adsorbed onto the charged micellar surface. Thus, by analyzing the effect on the ${}^{13}\text{C}$ relaxation along the chain, the distribution in the distance from the micellar surface could be estimated for the various methylene segments.

A conceptually similar study was reported recently by Palmas et al.⁶² Here, cross relaxation effects between ¹³C and nondirectly bonded protons were examined by two-dimensional heteronuclear Overhauser effect spectroscopy (HOESY). This study revealed the significance of intermolecular ¹H–¹³C dipolar interactions. Correlations between carbon atoms and protons belonging to different segments were observed in the lower part of the hydrocarbon chains, while they were found to be absent in the vicinity of the polar head-group, where the chain configuration is more rigid.

1 INTRODUCTION

Liquid crystals can be loosely defined as materials with properties intermediate between those of solids and liquids (mesophases). Liquid crystals typically flow like viscous liquids but the phase exhibits some degree of molecular packing or structure whereby individual molecules tend to align, making the mesophase anisotropic.

1.1 NMR in Liquid Crystalline Solvents

Most molecules that form a nematic mesophase are able to dissolve a small amount of solute compound without destroying the mesophase. Since the first reports of using liquid crystals as solvents for NMR spectroscopy, high resolution NMR in liquid crystalline solution has developed into an important area.¹ The amount of solute that can be dissolved in a nematic mesophase depends on the mesophase and the solute, but solute concentrations of 5 wt % are common and concentrations of 10–15 wt % are sometimes achievable without disrupting the liquid crystalline properties of the solvent.

The motion of solute molecules dissolved in a nematic mesophase is restricted by the arrangement of the mesophase molecules. The anisotropy of the arrangement of the solvent molecules induces anisotropy in the movement of the solute molecules via dispersion forces. A solute dissolved in an oriented mesophase is forced to undergo nonrandom (anisotropic) motion because of its interactions with the aligned solvent. If the nematic mesophase is aligned in a magnetic field then alignment of the mesophase is reflected in the anisotropy of the motion of the solute molecules.

The rapid motion of molecules in an oriented mesophase results in the averaging of the intermolecular dipolar interactions to zero. However, the intramolecular dipolar interactions have a nonzero average.

Qualitatively the NMR spectra of solutes oriented in mesophases are more complex than the spectra obtained in isotropic solvents, for two reasons (see *Liquid Crystalline Samples: Spectral Analysis*):

1. The nonzero averaging of dipolar couplings results in many more coupling constants (splittings) being expressed in the spectrum. A dipolar coupling constant appears for every pair of interacting nuclei.
2. The magnitude of the dipolar coupling constants (D_{ij}), between a pair of interacting nuclei is generally large (up to a few kilohertz) compared with the indirect coupling constants (typically a few hertz). This results in virtually all spectra of solutes dissolved in an oriented mesophase being highly second order and adds to the spectral complexity.

2 MULTIPLE QUANTUM NMR OF SAMPLES DISSOLVED IN LIQUID CRYSTALLINE SOLVENTS

The signals observed in a conventional NMR spectrum (single rf pulse followed by signal acquisition and FT of the resulting FID) are governed by selection rules which dictate that transitions can only be induced between energy levels differing in total spin quantum number by $\Delta M = \pm 1$ (single quantum transitions). Multiple quantum NMR (MQ NMR)² is concerned with the observation of nuclear transitions where $\Delta M \neq \pm 1$.

The number of transitions in the single quantum NMR spectrum of a solute dissolved in an anisotropic solvent increases rapidly with the number of coupled spins. A molecule with a single proton would have a ^1H spectrum with only one transition. A system containing two protons would have four possible transitions, and a spin system composed of three nonequivalent protons has 15 transitions.

The number of transitions for an unsymmetrical spin system (disregarding symmetry considerations) can be calculated as³

$$\text{No. single quantum transitions} = (2N)! / [(N-1)!(N+1)!] \quad (1)$$

This is an exponential function where the number of transitions increases dramatically as the number of interacting spins increases (Figure 1). In an 8-spin system there would be 1.14×10^3 transitions in the single quantum spectrum; in a 10-spin system there would be 1.67×10^5 transitions.

If there is symmetry present in the spin system (i.e. chemically or magnetically equivalent nuclei) the number of transitions is reduced. For the symmetrical six proton spin system of benzene there are 72 transitions, compared with 792 transitions in a six proton system with no symmetry.

Given a reasonable linewidth for each transition, substantial overlap occurs in the single quantum spectrum of a large spin system, and the spectrum rapidly degenerates to an unresolved broad lump. In higher spin systems, it becomes impossible to resolve or assign individual transitions for an iterative computer analysis. MQ NMR can considerably reduce the complexity of the spectrum of a solute dissolved in a liquid crystalline solvent, and the main benefit of MQ NMR lies in the fact that there are fewer transitions in the very high MQ spectra.

Figure 1 The number of single quantum transitions as a function of the number of interacting nuclei ($I = \frac{1}{2}$)

The number of M quantum transitions in a system of N nuclei ($I = 1/2$), neglecting symmetry, is given by

$$\text{No. of } M \text{ quantum transitions} = (2N)! / [(N - M)!(N + M)!] \quad (2)$$

Representative values are summarized in Table 1.

In the N quantum spectrum of an N -spin system, there will always be only one transition. The $(N - 1)$ quantum spectrum of an N -spin system will contain only $2N$ transitions. For large N , the $N - 1$ and $N - 2$ quantum spectra will contain only a few transitions and will be much less complex and more easily analyzed than the single quantum spectrum.

3 EXCITATION OF MULTIPLE QUANTUM COHERENCES

Coherence between states separated by $\Delta M \neq 1$ cannot be observed directly, but is usually detected indirectly by

its modulation of single quantum coherence in a two-dimensional NMR experiment. A two-dimensional NMR experiment⁴ for exciting and detecting MQ spectra can be divided schematically into five time frames, as shown in Table 2.

Providing that MQ coherences (MQCs) can be produced by a suitable preparation sequence, and mixed to observable single quantum coherence with an appropriate 'mixing' sequence, the MQ frequencies of a spin system can be obtained by systematically varying the duration of the 'evolution' period (t_1) followed by Fourier transformation over t_1 . Compared with samples in isotropic solution, MQCs can be excited relatively easily in samples dissolved in liquid crystalline solution. The large dipolar coupling constants expressed ensure that coherences evolve rapidly and MQC can be excited efficiently before the effects of relaxation complicate coherence development in the spin system.

3.1 Nonselective Excitation

The most common (and simplest) method for preparing MQC is by use of two $\pi/2$ pulses separated by a fixed delay. The simplest mixing sequence is a single $\pi/2$ pulse and this means that a three-pulse sequence (Figure 2) can be used to record multiple quantum spectra.

The sequence of two hard pulses in the preparation part in Figure 2 nonselectively generates coherence of all orders possible in the spin system. Coherences are not excited uniformly and the efficiency with which MQC is excited depends specifically on the couplings and chemical shifts of the nuclei in the spin system and the choice of the interval d_1 . Broad band excitation techniques have been proposed⁵ where the value of d_1 in the preparation sequence is varied either in a pseudorandom or systematic fashion to achieve a more uniform excitation in the multiple quantum domain. Weitekamp et al.⁶ have devised an experimental search procedure for optimizing the delays in the preparation period of the MQ excitation sequence.

Table 1 The Number of Transitions in the M Quantum Spectra as a Function of the Number of Interacting Nuclei ($I = \frac{1}{2}$)

ΔM	Number of spins ($I = \frac{1}{2}$)						
	2	4	6	8	10	15	20
1	4	56	792	11440	1.68×10^5	1.45×10^8	1.31×10^{11}
2	1	28	495	8008	1.26×10^5	1.19×10^8	1.13×10^{11}
4		1	220	1820	38760	5.46×10^7	6.28×10^{10}
6			1	120	4845	1.43×10^7	2.32×10^{10}
8				1	190	2.04×10^6	5.58×10^9
10					1	1.42×10^5	8.48×10^8
15						1	6.58×10^5

Table 2 The Five Time Frames in the Two-dimensional MQ NMR Experiment^a

Relaxation	Preparation	Evolution	Mixing	Detection
Spin system relaxes between experiments	Generate MQC in the coupled spin system	MQC evolves with time (t_1)	Mixes MQC to observable SQC	Detect SQC as a FID (t_2)

^aMQC, multiple quantum coherence; SQC, single quantum coherence.

Figure 2 Three-pulse sequence for the observation of MQ spectra

3.2 Selective Excitation

Nonselective excitation of MQC excites all possible coherences, but leaves most of the spectral intensity in the single quantum and low multiple quantum spectra because these spectra have the most transitions.^{3b} As a result, the simpler high-order coherences are comparatively weak. An alternative approach to the excitation of MQC is selectively to excite only a few orders of coherence and more effectively channel or focus the available signal into one order (or a few selected orders).

Order selective excitation has been achieved by the use of phase-cycled sequences of rf pulses⁷ and composite pulse trains.⁸ Pines et al.^{7,9} have established that an nk quantum selective excitation sequence ($k = 0, \pm 1, \pm 2, \dots$) can be constructed by repeating an appropriate sequence with a phase increment $2\pi/n$ between repetitions:

$$\begin{aligned} \varphi = 0 \quad \varphi = 2\pi/n \quad \varphi = 4\pi/n \quad \varphi = 2(n-1)\pi/n \\ [p_1 \dots p_q] [p_1 \dots p_q] [p_1 \dots p_q] \dots [p_1 \dots p_q] \end{aligned}$$

The pulse sequences $[p_1 \dots p_q]$ employed in each section of the sequence can be nonselective; however, only certain sequences are effective in efficiently generating the desired orders of MQC. Sequences involving several thousand cycled pulses have been explored.^{7,9} An upper limit on the length of the excitation sequence is set by relaxation processes in the spin system. Effective phase-cycled excitation sequences must generate MQC efficiently and compensate for the effects of imperfect rf hardware and pulses.

4 DETECTION OF MULTIPLE QUANTUM COHERENCES

The frequencies of MQCs are obtained indirectly using two-dimensional NMR sequences whereby the multiple quantum frequencies modulate the observable single quantum spectrum. The two-dimensional spectrum contains multiple quantum frequencies in F_1 and single quantum frequencies in F_2 . The frequencies of the multiple quantum spectrum are most conveniently obtained as F_1 projections from the two-dimensional spectrum.

It is not necessary to acquire an entire two-dimensional data set to obtain the multiple quantum frequencies. MQ spectra can be obtained by acquiring a single point in t_2 (at $t_2 = 0$ or some other value) and then transforming the resulting one-dimensional sequence of points as a function of t_1 . In theory, the FT of the $t_2 = 0$ row of a two-dimensional data set is identical to the F_1 projection of the entire two-dimensional data set.¹⁰

If the MQ preparation sequence does not perfectly select coherences from an individual MQ order, then the MQ spectrum detected will be a complex superposition of subspectra from the various MQCs excited. There are several methods available to filter or separate the MQ spectra of various orders.

4.1 Order Selective Detection

4.1.1 Dependence on Resonance Offset

n Quantum coherence evolves n -fold more rapidly during the t_1 evolution period of the MQ experiment than does single quantum coherence. If the single quantum spectrum is centered at a frequency approximately $\Delta\omega$ from the rf transmitter, transitions in the n quantum spectrum are centered at a frequency $n\Delta\omega$. With nonselective excitation, multiple quantum spectra are separated by $\Delta\omega$ and by judicious selection of the transmitter offset, the spectra of various multiple quantum orders can be cleanly separated (Figure 3) in the frequency domain.

The main disadvantages of using transmitter offsets to separate various orders of MQC are: (i) offset frequencies of 10–30 kHz are often required to obtain clean separation of the coherence orders and the large offset results in nonuniform rf distribution and homogeneity across the spectrum; and (ii) for a nonselective experiment where all orders of coherence (up to $\pm N$ orders in an N -spin system) are detected, the total sweep width required in F_1 is prohibitively large. The F_1 sweep width is approximately $N \cdot SW$, where SW is the approximate spectral width of any of the orders of coherence in the spin system; SW may be 100–300 kHz and necessarily gives rise to poor digital resolution.

4.1.2 Time Proportional Phase Incrementation

Time proportional phase incrementation (TPPI) enables the separation of spectra of various coherence orders. If the phase of the excitation radiation is incremented by $\Delta\phi = \Delta\omega \cdot \Delta t_1$ each time that t_1 is incremented by Δt_1 , the n quantum spectrum is centered at a frequency $n\Delta\omega$ from the transmitter in the two-dimensional MQ NMR spectrum. MQ orders are separated in frequency by $\Delta\omega$ in the same fashion as if an offset had been employed.

4.1.3 Order Selective MQ Filtration Using Phase Cycling

Order selective detection of the spectrum of a desired order n is achieved by coadding $4n$ FIDs at each value of τ_1 with the phase of the preparation rf radiation (φ_1 in Figure 2) incremented from $2\pi/4n$ to 2π in steps of $2\pi/4n$ with the receiver phase (φ_3 in Figure 2) incremented by $\pi/2$ at each step.¹¹ Two-dimensional Fourier transformation over τ_1 and τ_2 affords a two-dimensional spectrum which has the MQ

Figure 3 The separation of MQ spectra by employing a transmitter offset: ^1H spectrum of 2-methylthiophene aligned in a liquid crystalline solvent. The spectrum was acquired with the pulse sequence shown in Figure 2 with the transmitter offset approximately 20.7 kHz from the center of spectrum. The full spectrum is symmetrical about $F_1 = 0$ and only half of the spectrum is shown. Frequencies in the MQ spectrum are obtained from an F_1 projection of the two-dimensional data set

frequencies of the desired order of MQC in F_1 and the MQ filtered single quantum spectrum in F_2 .

4.1.4 Coherence Echo Filtration

Order selective detection of the spectrum of a desired order n has been achieved by exploiting the phase properties of MQC transfer echoes. An additional (fixed) period d_e is inserted in the MQ pulse sequence, prior to the mixing pulse of the MQ pulse sequence (Figure 4). The delay d_e results in the MQCs evolving beyond the normal τ_1 period and coherence transfer echoes of the n quantum coherences

maximize in the detection period at nd_e .¹² Different coherence orders give rise to echoes which maximize at different times in the detection period. The spectra derived from individual orders of coherence can be obtained by selecting a detection window to coincide with the maximum signal of the desired order of coherence.

4.1.5 Use of Magnetic Field Gradients

Order selective detection of the spectrum of a desired order n has been achieved by using field gradients.¹³ A field gradient pulse of amplitude g is applied at the end of the MQ evolution

Figure 4 Pulse sequence for selectively observing MQC transfer echoes

period, prior to the mixing section of the MQ pulse sequence (Figure 5). A refocusing gradient of amplitude ng immediately after the mixing sequence selects only signals from the n -quantum spectrum.^{12a, 14}

4.1.6 Phase Sensitive MQ Spectra

A disadvantage of most simple mixing sequences which convert MQCs to detectable single quantum coherence is that the detectable single quantum spectrum has both absorption and dispersion components. As spin systems become larger, the single quantum spectrum degenerates to a mass of overlapping resonances, and any mixing sequence which results in signals of differing phase causes signal cancellation. In larger, more complex spin systems, the single quantum spectrum becomes weaker and inherently more difficult (or impossible) to detect. Pines et al.¹⁵ have developed a general class of MQ experiments where the MQ preparation sequence is matched with a mixing sequence (a time reversal sequence) to give a single quantum spectrum which is in-phase. There are a number of matched preparation/mixing sequences and these have been used to observe high-order MQ spectra, including those in solids.

Another consequence of simple MQ sequences is that the MQ spectra obtained are obtained as spectra that cannot be phased. Most MQ spectra which have been recorded from samples dissolved in liquid crystalline solution have been transformed as magnitude spectra. Using appropriately matched preparation and mixing sequences, pure absorption spectra

have been recorded,^{2b, 16} and these show improved sensitivity and resolution compared with corresponding magnitude spectra.

5 METHODS OF SPECTRAL ANALYSIS AND SPECTRAL SIMULATION

The energy levels of an n -spin system can be calculated if the dipolar coupling constants D_{ij} , scalar coupling constants J_{ij} , chemical shifts ν_i , and quadrupolar coupling constants q_{ij} are known. The energy levels are grouped into manifolds according to their Zeeman quantum number (M) and irreducible symmetry representations. m Quantum transitions occur between energy levels of the same symmetry where $\Delta M = m$. The frequencies of MQ transitions are not difficult to calculate and the frequencies in experimental MQ spectra have been fitted iteratively to calculated frequencies using modifications of LAOCOON type¹⁷ computer algorithms. The calculation of the correct intensities of MQ transitions is more demanding since the transition intensities are a complex function of the specific pulse sequence used to generate the spectrum. Transition intensities in MQ spectra derived from a simple three-pulse sequence (Figure 2) have been estimated using a statistical approach whereby all symmetry-allowed transitions are assumed to be equally excited. Averaging over a range of d_1 values, the integrated intensity per order decreases as ΔM increases, but the average intensity per transition increases as ΔM increases.^{3b} The estimation of transition intensities in MQ spectra has been extended to excitation sequences involving order selective composite pulse excitation, and the calculations provide a reliable means for theoretically optimizing the efficiency of the excitation sequence.¹⁸

6 APPLICATIONS OF MQ NMR TO SAMPLES DISSOLVED IN LIQUID CRYSTALLINE SOLVENTS

6.1 Structural Studies

In the spectra of compounds dissolved in liquid crystalline solution, dipolar interactions between nuclei are not averaged to zero and the spectra can, in principle, be analyzed to obtain values for the dipolar coupling constant D_{ij} between each pair of nuclei (i and j) in the solute spin system. Since the D_{ij} are inversely proportional to the cube of the internuclear distances r_{ij} [equation (3)], the relative positions of the nuclei in the spin system can be determined and the shape of the molecule as well as its average orientation in the magnetic field can be deduced, providing enough independent D_{ij} values can be measured. For a system of coupled $I = 1/2$ nuclei, the transition frequencies in the MQ spectra are determined by the dipolar coupling constants, the scalar coupling constants, and the chemical shifts of the nuclei. In theory, the spectra of order $n - 1$ and $n - 2$ contain sufficient transitions to measure all the dipolar coupling constants and chemical shifts in an n -spin system:

$$D_{ij} = -(h\gamma_H^2/4\pi^2)S_{ij}/r_{ij}^3 \quad (3)$$

where γ_H is the proton magnetogyric ratio, r_{ij} is the internuclear distance between protons i and j , and S_{ij} is the order of the internuclear vector between i and j .¹⁹ There have been only a few studies in which the geometry of a spin system has been established using MQ NMR.

6.1.1 Structure of Rigid Molecules: Structure of 1-Bromonaphthalene

1-Bromonaphthalene has a proton spin system containing seven nonequivalent spins. In liquid crystalline solution the ^1H NMR spectrum contains more than 3000 transitions (Figure 6).²⁰ The five and six quantum spectra have been recorded and solved simultaneously (Figure 7) to give values for the 21 independent dipolar coupling constants, and from the D_{ij} values the geometry of the planar seven spin system was determined.²⁰

6.1.2 Chain Mobility in *n*-Hexane- d_6

MQ NMR has been employed to study chain mobility in alkanes dissolved in liquid crystalline solution. Drobny^{2b} has reported the MQ spectra of *n*-hexane- d_6 (deuterated in the terminal methyl groups) dissolved in a nematic solvent. MQ spectra were recorded and the high quantum spectra (six and seven quantum) analyzed to give dipolar couplings. The six quantum proton spectrum contains 36 transitions and the seven quantum spectrum contains four transitions, as expected for an eight proton spin system with C_{2h} symmetry. The best fit of theoretically generated MQ NMR spectra to the experimental spectra was obtained with a model where only the minimum energy conformations of the alkane chain were appreciably populated.

6.1.3 Structure of 4-Cyano-4'-*n*-pentylbiphenyl

4-Cyano-4'-*n*-pentylbiphenyl is a nematic liquid crystal at room temperature. The five, six, and seven quantum MQ NMR spectra of the eight proton spin system of a partially deuterated compound (with the pentyl side chain completely deuterated) have been analyzed to give the interproton dipolar couplings in the biphenyl core of the molecule.²¹ The best match between the experimental and simulated MQ NMR spectra were obtained when the biphenyl system was not planar, but when there was an angle of about 32° between the linked phenyl groups.

6.2 Counting Spins in Clusters

In MQ NMR, individual spins become correlated with each other over time through their dipolar couplings. The rate at which MQCs develop is a complex function of the coupling constants present in the spin system. In solids, where the distribution of dipole coupled spins is effectively infinite, the correlations between spins develop in a monotonic fashion. As time progresses, more spins can absorb more quanta and high order MQC can be generated.²² In systems where there are effectively isolated clusters of spins (e.g. liquid crystals, molecules dissolved in liquid crystalline phases, and polycrystalline solids) the time development of MQC is

Figure 8 The effective system size $N(\tau)$ as a function of the preparation time τ for the liquid crystal 4-cyano-4'-heptylbiphenyl. After an induction period of approximately $1000\ \mu\text{s}$, $N(\tau)$ levels off to a value of 21, reflecting the number of spins in the isolated molecular cluster. Reprinted by permission of the American Chemical Society from Baum and Pines²²

interrupted and the system can only support MQC up to the size of coupled spin clusters. In the 21-spin system of the liquid crystal 4-cyano-4'-heptylbiphenyl, the effective spin system size increases to a maximum of 21 spins as the preparation time for MQC increases (Figure 8).

The rate of MQC development in a mixture of liquid crystalline materials has also been used to identify and observe distinct subsections of molecules comprising the liquid crystals. Separate MQ signals were observed for effectively isolated spin pairs (phenyl rings) and weakly coupled multispin clusters (alkyl tails)²³ in a mixture of 4-cyanophenyl 4'-butylbenzoate and 4-cyanophenyl 4'-heptylbenzoate.

6.3 Measurements of Diffusion

MQC has been used to extend the normal NMR spin echo measurement of diffusion. In typical spin echo experiments, molecules are labeled by their position in a magnetic field gradient after an initial rf pulse and diffusion is measured by monitoring the amplitude of the spin echo following a second pulse. MQ NMR spectroscopy exploits the fact that n quantum coherence dephases n -times more quickly than does single quantum coherence, so higher quantum coherences are significantly more sensitive to diffusion.

Martin et al.²⁴ measured the diffusion of dichloromethane (CH_2Cl_2) in various liquid crystal solvents by following the decay of the double quantum coherence. In measurements of the diffusion of benzene in a nematic liquid crystal, Zax and Pines²⁵ used a pulse sequence [Figure 9(a)] to excite MQC nonselectively and then selectively monitored the decay of the coherence echo of the $n = 1$ to $n = 6$ orders of coherence following field gradient pulses. The amplitude of echo decay for all orders of coherence was fitted to a modified Stejskal-Tanner equation²⁶ (Figure 9), thus verifying that the rate of echo decay is proportional to n^2 .

6.4 Molecular Motion and Relaxation

The spectral densities of molecule motion $J_q(\omega)$ are usually estimated by simultaneously analyzing a combination of

Figure 9 (a) Pulse sequence for an NMR pulsed field gradient experiment. (b) Normalized echo amplitudes plotted against the gradient pulse timing parameter $[\delta^2(\Delta - \delta/3)]$ of the Stejskal-Tanner equation.²⁶ (Reproduced by permission from D. Zax and A. Pines, *J. Chem. Phys.*, 1983, **78**, 6333)

relaxation measurements. Spectral densities may be measured from the decay of MQC and, particularly in $I = 1$ systems where the relaxation mechanism is dominated by the nuclear quadrupole, the relaxation of zero, double, triple and higher order coherences have been used to determine the spectral densities of motion for small deuterated organic molecules (CDCl_3 ,²⁷ $\text{D-C}\equiv\text{C-C}\equiv\text{N}$,^{27b}, CD_2Cl_2 ,²⁸ and $\text{CD}_3\text{-C}\equiv\text{N}$,²⁹) dissolved in liquid crystalline solution. The relaxation of the two and three quantum resonances of ^{23}Na ($I = \frac{3}{2}$) and the four and five quantum resonances of ^{17}O ($I = \frac{5}{2}$) have been measured in lyotropic liquid crystals.³⁰

6.5 Heteronuclear MQC

Heteronuclear MQC (HMQC) (coherence involving spins of different type, e.g. $^1\text{H}/^2\text{H}$ or $^1\text{H}/^{15}\text{N}$) have been used to study molecules in liquid crystal solution. Minoretti et al.³¹ have demonstrated that there is a significant sensitivity advantage when the MQCs of a relatively insensitive nucleus (e.g. ^2H) can be detected indirectly by observing ^1H nuclei coupled to the heteronuclear spin system.

1 INTRODUCTION

Nuclear magnetic resonance studies of liquid crystals confined to submicrometer cavities of polymer dispersed liquid crystals (PDLC) pose problems of both basic and applied interest. The high surface-to-volume ratio imposed by the cavities and the high density of cavities present in the confining matrices allow for NMR studies of unusual surface phenomena not possible before the development of this powerful experimental technique. Unique measurements of surface molecular anchoring energies and angles, effects of surface confinement on molecular orientational ordering, and surface layer transitions predicted by theory are shown to be accessible by this method. Nematic director configurations and pretransitional ordering at cavity surfaces are the subject of this article.

Golemme and co-workers¹ pioneered NMR studies of confined liquid crystals in PDLCs. Using composites of polymer and spherical liquid crystal droplets composed of low molecular weight liquid crystal (selectively deuterated) of uniform size ranging from 2.0 to 0.02 μm in diameter, they were able to use deuterium NMR to study the molecular orientational order parameter of the confined liquid crystal. The results revealed that, for sufficiently small droplets, the isotropic fluid phase is replaced by a paranematic phase where a small but finite amount of order persists and that the nematic–isotropic transition is replaced by the continuous evolution of orientational order. Golemme and co-workers² also presented an elegant study of the nematic director fields that are stable in spherical cavities below the nematic–isotropic transition. This work prompted researchers³ to study the molecular dynamics of liquid crystal molecules under spherical confinement and to develop further the theory of ordering within spherical geometries.

The successful work on liquid crystal droplets led to subsequent studies of confined liquid crystals in other cavity shapes and sizes. The study of nematic liquid crystal director fields was extended⁴ to submicrometer cylindrical cavities of diameter 0.6 and 0.4 μm , demonstrating the effectiveness of this technique in confirming nematic director configurations in high detail to the point of even identifying singular defect

structures and their densities. Confining liquid crystals to cylindrical rather than spherical cavities has two distinct advantages: the internal cavity surfaces are easily modified by chemical treatments that alter the molecular anchoring energies and angles at the cavity wall, and the cylindrical symmetry simplifies the analysis of the deuterium NMR spectra. Deuterium NMR has proven to be the most effective experimental tool in probing the ordering effects of confined liquid crystals, and has furthered the understanding of these systems to the point of being useful in optimizing the performance of electrooptic displays that rely on confinement.⁵

2 CONFINING MATERIALS

There are two ways in which liquid crystals have been prepared for NMR experiments. The phase separation technique is used to form spherical liquid crystal droplets surrounded by a polymer where diameters can be controlled down to 0.02 μm in diameter.⁵ The most common liquid crystal used for deuterium NMR experiments on confined liquid crystals is 4'-pentyl-4-cyanobiphenyl (5CB), either deuterated in the α - or β -position of the hydrocarbon chain. The liquid crystal is usually soluble in the polymer or prepolymer, and after polymerization occurs, the liquid crystal phase separates out to form nearly spherical droplets. The size of the droplets can be adjusted by varying the relative amounts of the liquid crystal to the polymer or by varying the cure temperature; for instance, less liquid crystal in the solution leads to more rapid polymerization, which reduces the droplet size. Scanning electron microscope (SEM) photographs of the spherical cavities found in the polymer matrix are presented in Figure 1(a).

The other technique used to confine liquid crystals is to permeate a prefabricated porous matrix with a deuterated liquid crystal. These matrices are commercially available with either well-defined or random-type cavities. The pores of Nuclepore membranes, presented in Figure 1(b), and those of Anopore membranes, presented in Figure 1(c), are well-defined cylindrical channels. Nuclepore membranes are fabricated from 10 μm polycarbonate sheets in a variety of pore sizes, ranging between 12 and 0.015 μm , with a 12% porosity. An important property inherent to Nuclepore membranes is the presence of corrugations on the inner cavity walls, which prove useful for uniform homogeneous alignment. Anopore membranes are alumina-based membranes available only in 0.2 μm pore sizes, but with a porosity of nearly 40%, a thickness of 60 μm , and an extremely narrow pore size distribution. Anopore membranes have advantages compared with Nuclepore membranes because they are easier to handle when preparing an NMR sample, and their larger porosity gives rise to a better signal-to-noise ratio. However, they are only manufactured in the 0.2 mm pore size, whereas Nuclepore membranes are available in a large variety of pore sizes. For a sufficient signal-to-noise ratio, approximately forty 5 mm $\times$ 25 mm sheets of permeated Anopore membranes or nearly two hundred 5 mm $\times$ 25 mm sheets of permeated Nuclepore membranes stacked uniformly and secured in a 5 mm NMR sample tube are required. Both Nuclepore and Anopore membranes can be filled with most liquid crystals. The material dodecylcyanobiphenyl (12CB) deuterated in the α position was also used in these matrices to study the effect of confinement

Figure 1 Scanning electron microscope photographs of various types of matrices used to confine liquid crystals. (a) The polymer matrices of PDLC materials with spherical inclusions are shown for two different droplet sizes formed by polymerization-induced phase separation techniques. (b) Nuclepore membranes with cylindrical inclusions are shown for two different pore sizes; the close-up photograph of the inner polymer surface of the pore reveals corrugations. (c) Anopore membranes are alumina-based matrices that consist of 0.2 mm cylindrical pores; the cross-sectional photograph reveals the cylindrical nature of the pore and its narrow pore size distribution. The structures of two of the deuterated liquid crystalline compounds commonly used in confinement studies are shown at the bottom

on the smectic A–isotropic transition temperature. There are comprehensive reviews of the properties of these membranes,⁶ as well as of those matrices that exhibit a random-type confinement.⁷

3 DEUTERIUM NMR OF CONFINED LIQUID CRYSTALS

The molecular orientational order in confined liquid crystals strongly influences the deuterium NMR lineshape. Because of the positional dependence of the molecular orientation and orientational order parameter in confined liquid crystals, molecular self-diffusion can induce additional motional averaging. Considering typical values for the translational diffusion constant for nematic liquid crystals $D \approx 10^{-11} \text{ m}^2 \text{ s}^{-1}$, and for

a cavity diameter on the order of $1 \mu\text{m}$, the influence of self-diffusion is significant for splittings below 1 kHz, while spectra with splittings in the 100 kHz range will not be affected by diffusion. Neglecting averaging effects caused by translational motions and in a frame determined by the external magnetic field $\mathbf{B}$, the quadrupole splitting for a nucleus with spin $I = 1$ at the position $\mathbf{r}$ can be expressed by the following relationship:⁸

$$\delta\nu = \frac{1}{2} \frac{S(\mathbf{r})}{S_B} \delta\nu_B \{ [3 \cos^2 \theta_n(\mathbf{r}) - 1] + \eta(\mathbf{r}) \sin^2 \theta_n(\mathbf{r}) \cos[2\psi_n(\mathbf{r})] \} \quad (1)$$

where $\theta_n(\mathbf{r})$ and $\psi_n(\mathbf{r})$ express the orientation of $\mathbf{B}$ in the principal axis frame of the local electric field gradient (EFG) tensor averaged over fast orientational fluctuations, S_B and $\delta\nu_B$ are the orientational order parameter and the quadrupole splitting frequency of the bulk liquid crystal material, respectively, and $S(\mathbf{r})$ is the local order parameter at position $\mathbf{r}$ inside the cavity. The bulk quadrupole splitting frequency $\delta\nu_B$ is directly proportional to the degree of orientational order of the C–D bond direction with respect to $\mathbf{B}$.⁸ The asymmetry parameter $\eta(\mathbf{r})$ is zero for uniaxial liquid crystals, but can be nonzero for confined liquid crystals because the averaging motions (orientational fluctuations) lose their symmetry under confinement. The effect is predicted to be small;⁹ therefore, $\eta(\mathbf{r})$ is typically neglected.

The analysis of spectra recorded for nematic liquid crystals confined to cavities of diameters ranging between 0.1 and $1.0 \mu\text{m}$ is simplified for the following three reasons. The characteristic diffusion length is approximately $d \approx (D/\delta\nu)^{1/2} \approx 0.02 \mu\text{m}$ for $D \approx 10^{-11} \text{ m}^2 \text{ s}^{-1}$ and $\delta\nu \approx 50 \text{ kHz}$, which is substantially less than the cavity diameters; therefore, the deuterium NMR spectra are indicative of the director distribution. The aligning effect of $\mathbf{B}$ on the nematic directors is negligible because the magnetic coherence length $\xi_m \approx (\mu_0 K / \Delta\chi)^{1/2} / B \approx 1.7 \mu\text{m}$ is substantially larger than the cavity diameters for typical values of the bulk elastic constant K and diamagnetic susceptibility $\Delta\chi$ for the 5CB compound when a 4.7 T magnetic field is employed. The order parameter can also be taken as constant throughout the cavity volume: $S(\mathbf{r}) = \text{constant} = S_B$ in the nematic phase for these cavity sizes.⁴ The deuterium NMR spectral distributions are calculated from the free induction decay (FID), which is a function describing the attenuation of nuclear magnetization in the time domain. The FID is described in terms of the resonance frequency expressed by equation (1) given by the following relationship:¹⁰

$$G(t) = \left\langle \exp \left\{ i \int_0^t \pi \delta\nu[r(t')] dt' \right\} \right\rangle = \sum_j \exp[i\pi \delta\nu(r_j)t] P(r_j) \quad (2)$$

where the time interval $(0, t)$ is divided into equal parts, $\langle \rangle$ represents the ensemble average, and P is the time-independent probability that there is a molecule with frequency $\delta\nu$ at position r_j . The frequency spectrum is obtained by the Fourier transformation of equation (2) given by the expression

$$I(\delta\nu) = \int_{-\infty}^{\infty} G(t) \exp(-i\pi \delta\nu t) dt \quad (3)$$

Line broadening is included by convoluting $I(\delta\nu)$ with the Gaussian distribution function. Motional averaging can be included in this formalism, if necessary, by incorporating an instantaneous value of the quadrupole splitting frequency and time-dependent probability in equation (2).

In the isotropic phase, confined liquid crystals in submicrometer cavities exhibit a small but measurable quadrupole splitting frequency due to the induced order at the cavity wall. In this case, the characteristic diffusion length $d \approx (D/\delta\nu)^{1/2} \approx 0.3 \mu\text{m}$ now becomes comparable to the cavity radii, resulting in spectra that are motionally averaged. Furthermore, the orientational order parameter depends on position r . Assuming $S(r) = S_0 \exp[-(R-r)/\xi]$ for a liquid crystal confined to a cylindrical cavity of radius R , where R is comparable to the characteristic diffusion length, the time-averaged quadrupole splitting frequency can be expressed as

$$\langle\delta\nu\rangle = \frac{\delta\nu_B}{S_B} \langle S \rangle = \frac{\int_0^R S(r)r dr}{\int_0^R r dr} = \frac{2\delta\nu_B S_0 \xi}{S_B R} \quad (4)$$

where S_0 is the orientational order parameter of the molecules at the surface and ξ is the penetration length of nematic-like order, which propagates away from the cavity wall. Far from the cavity wall of the confining cylinder, $S(r)$ is zero, and the quadrupole interactions are completely averaged. Equation (4) demonstrates the usefulness of deuterium NMR as a tool for probing surface-induced phenomena.

4 PROBING NEMATIC DIRECTOR CONFIGURATIONS

Deuterium NMR is useful for identifying nematic director fields inside confined geometries. One example is presented in Figure 2 for the liquid crystal material 5CB- βd_2 confined to the 0.4 and 0.5 μm cavities of Nuclepore membranes. Before the liquid crystal was filled into the pores of Nuclepore membranes, however, the pores were rinsed with a lecithin solution to promote perpendicular aligning conditions of the liquid crystal molecules at the cavity wall. One advantage of cylindrical pores in Nuclepore and Anopore membranes is that they can be placed in different orientations within the magnetic field to double-check nematic director distributions and remove ambiguity in the deuterium NMR measurement. Two orientations were studied: $\theta_B = 0^\circ$ and 90° , corresponding to the cylinder axis being parallel and perpendicular to the magnetic field, respectively. For the 0.4 μm sample, the $\theta_B = 0^\circ$ orientation resulted in a splitting that is $\frac{1}{2}\delta\nu_B$, and the $\theta_B = 90^\circ$ orientation resulted in a splitting that is identical to $\delta\nu_B$, with a slight broadening inside the peaks. For the 0.5 μm sample, the $\theta_B = 0^\circ$ orientation has a splitting of $\frac{1}{2}\delta\nu_B$, with a significant contribution in the center of the spectrum, and the $\theta_B = 90^\circ$ orientation appears to be a cylindrical powder pattern. The change in the spectral patterns as the pore size is changed indicates that a nematic director field configuration transition¹¹ has taken place.

To help in analyzing the spectral patterns in Figure 2, Frank elastic theory was employed to predict the stable director field,

Figure 2 Experimental deuterium NMR spectra (solid line) of 5CB- βd_2 in the cylindrical pores of Nuclepore cavities fitted to theoretical spectra (dotted line) simulated from director distributions derived from elastic theory. Parallel ($\theta_B = 0^\circ$) and perpendicular ($\theta_B = 90^\circ$) orientations of the cylinder axis in the magnetic field are recorded for two samples with different pore sizes. The director field distributions that are consistent with the spectra are the planar-polar (PP) and the escaped-radial (ER) configurations

which is expressed as

$$F = \frac{1}{2} \int_{\text{vol}} \{K_{11}(\nabla \cdot \mathbf{n})^2 + K_{22}(\mathbf{n} \cdot \nabla \times \mathbf{n})^2 + K_{33}(\mathbf{n} \times \nabla \times \mathbf{n})^2 - K_{24}\nabla(\mathbf{n} \times \nabla \times \mathbf{n} + \mathbf{n} \cdot \nabla \cdot \mathbf{n})\} dV + \frac{1}{2} \int_{\text{surf}} W_0 \sin^2 \phi dS \quad (5)$$

where $\mathbf{n}$ represents the nematic director, K_{11} , K_{22} , and K_{33} are the splay, twist, and bend phenomenological elastic constants, and K_{24} is the saddle-splay surface elastic constant; ϕ is the molecular anchoring angle of the liquid crystal molecules with respect to the cavity wall normal, and W_0 is its associated interaction energy (surface anchoring energy). Using this phenomenological expression, stable nematic director fields were derived, and are presented in Figure 2, along with their corresponding spectral patterns (dotted line), which are overlaid on the experimental spectra (solid line). The fitting parameter for the planar-polar (PP) director field stable in the $R = 0.4 \mu\text{m}$ cavities is RW_0/K ; therefore, the surface anchoring strength was determined to be $W_0 = 3 \times 10^{-5} \text{ J m}^{-2}$ for $K_{11} = K_{22} = K_{33} = K = 5 \times 10^{-12} \text{ J m}^{-1}$. The fitting parameter for the escaped-radial (ER) director field stable in $R = 0.5 \mu\text{m}$ cavities is $\sigma = RW_0/K + K_{24}/K - 1$, which allows the determination of $K_{24}/K \approx 1$ using the value of RW_0/K determined from the PP configuration. Using this value of W_0/K is justified, since the surfaces are identical. Measuring K_{24} was a great feat¹² in liquid crystal physics, because its magnitude eluded measurement for many years. There have been other studies in Nuclepore cavities for different

boundary conditions¹³ and liquid crystal materials,¹⁴ which have furthered the understanding of interfacial phenomena of liquid crystals and finite-size effects.

5 DETECTION OF SURFACE ORDERING

Deuterium NMR is a very powerful tool for studying surface-induced orientational ordering of liquid crystals in the isotropic phase. It can be used to determine the orientational order parameter at the surface and how far inside the cavity the order penetrates. For a truly isotropic phase, the quadrupole interactions average out and there is no quadrupole splitting—hence no orientational order. When the liquid crystal compound 5CB- βd_2 is confined to a small cavity, such as a Nuclepore cavity of radius $0.1\ \mu\text{m}$, a small but finite quadrupole splitting exists, indicative of surface-induced orientational order¹⁵ (see Figure 3). As the cylinder size decreases, the quadrupole splitting frequency increases in the isotropic phase because of the increased surface-to-volume ratio. The simple order parameter profile $S(r) = S_0 \exp[-(R - r)/\xi]$ does not describe the complete temperature dependence of the quadrupole splitting frequency. In fact, when the system is deep in the isotropic phase, a quadrupole splitting frequency still persists that is not predicted by theory. Such behavior is expected, however, when the dominant ordering interactions are local in nature. Better agreement between theory and experiment can be obtained by assuming a constant order within the first layer ($= S_0$) with a thickness equal to the

molecular length followed by the exponential decay of the order parameter profile as shown in Figure 3. This model enables good fits between experiment (solid line) and theory (dashed line) in Figure 3, and describes the strong quadrupole splitting frequency observed deep in the isotropic phase.¹⁵

Additional evidence of different behavior in the first molecular layer comes from the positional dependence of the self-diffusion constant, which can be determined by simultaneously fitting the spectra of different pore sizes. As shown in Figure 3, the shaded region at the surface of the cylinder represents a different self-diffusion constant, which is used to explain the broadening in the lineshapes as the pore size is decreased. This enables the measurement of the molecular exchange rate between the surface layer, which is found to be on the order of $10^3\ \text{s}^{-1}$. Similar experiments were performed using Anopore membranes¹⁶ as the confining matrix.

Recently, deuterium NMR was used to show that the surface order parameter at the cavity wall of Anopore membranes could be controlled systematically. By treating the membranes with an aliphatic acid surfactant $\text{C}_n\text{H}_{2n+1}\text{COOH}$, the ordering of the 5CB- αd_2 liquid crystal molecules at the cavity wall was found to depend strongly on the length (carbon number n) of the aliphatic surfactant that attaches itself to the alumina Anopore surfaces. For $n = 7, 9$, and 15 , perpendicular anchoring of the liquid crystal molecules was found to exist at the cavity walls, while for shorter chain lengths $n = 5$ and 6 , parallel anchoring of the liquid crystal molecules at the surface was preferred.¹⁷ In addition, the orientational order parameter at the cavity wall in the isotropic phase was found to increase with n for homeotropic anchoring conditions, while the reverse trend was observed for parallel anchoring. This was attributed to the interaction of the long alkyl chains of the aliphatic acid surfactant and the liquid crystal molecules being predominately sterical, resulting in perpendicular anchoring, while for shorter aliphatic chain lengths, strong interactions between the core of the liquid crystal molecules and the alumina Anopore surfaces enforced parallel anchoring conditions.

The temperature dependence of the quadrupole splitting in these systems was monitored, and the surface-induced orientational order parameter at cavity wall above the nematic–isotropic transition temperature (T_{NI}) was derived using a phenomenological free energy density in terms of the orientational order parameter. The data (derived from quadrupole splitting) and corresponding theoretical fits (solid line) are presented in Figure 4. For $n = 15$, the order parameter approaches $S_0 = 0.1$ near T_{NI} , which is still less than the bulk nematic order parameter at the transition, which is about 0.3 . However, the $n = 5$ sample that promotes parallel anchoring conditions shows a noncritical behavior in S_0 , which is found to be negative. A negative S_0 implies that the liquid crystal molecules are anchored with their long axis parallel to the surface by random orientation; therefore, the director is perpendicular to the surface, resulting in a negative S_0 .¹⁷ Deuterium NMR cannot directly distinguish whether S_0 is positive or negative, but the model can decipher its sign based on the temperature dependence of S_0 , i.e., the temperature dependence of $\langle\delta\nu\rangle$.

Deuterium NMR can be used to study a very interesting surface parameter that characterizes the wetting regime of the confined liquid crystal system. The adsorption parameter is defined as $\Gamma = \int_0^\infty [S(z) - S_B]dz$, where z is the distance

Figure 3 Experimental deuterium NMR spectrum (solid line) of 5CB- βd_2 in Nuclepore cavities above the nematic–isotropic transition temperature fitted to theoretical prediction (dotted line) is shown, lower right. The quadrupole splitting frequency $\delta\nu$ as a function of pore size recorded just above the nematic–isotropic transition temperature ($T - T_{\text{NI}} = 0.5\ \text{K}$) is shown (lower left). The model that describes the data includes a variation in the orientational order parameter S (upper left) and an inhibited diffusion constant at the cavity surface (upper right)

Figure 4 The orientational order parameter S_0 at the cavity surface of 5CB- αd_2 confined to the cylindrical channels of Anopore membranes derived from the measured quadrupole splitting frequency $\langle \delta\nu \rangle$ (inset). The channels of the Anopore membranes were modified with an aliphatic acid surfactant ($C_nH_{2n+1}COOH$) to introduce different interactions between the 5CB- αd_2 molecules and the surface. This is apparent from the dramatic temperature behavior of $\langle \delta\nu \rangle$ and S_0

from the cavity wall. Γ diverges for complete wetting, and remains finite for partial wetting at the nematic–isotropic transition temperature. This adsorption parameter is easily related to the averaged quadrupole splitting frequency¹⁷ by $\Gamma = RS_B \langle \delta\nu \rangle / 2\delta\nu_B$. According to theory,¹⁷ Γ exhibits a logarithmic divergence at the nematic–isotropic transition temperature for complete wetting; therefore, graphing $\langle \delta\nu \rangle$ on a semilogarithmic plot as shown in the inset in Figure 4 helps characterize the orientational wetting behavior. It appears that Γ exhibits weak divergence corresponding to complete wetting for the $n = 15$ surface; however, Γ definitely remains finite for the $n = 5$ surface. This provides an ideal way to characterize pretransitional orientational wetting behavior.

The power of deuterium NMR as a surface-sensitive technique is obvious from Figure 5. The average quadrupole splitting frequency in the isotropic phase of the liquid crystal compound 12CB- αd_2 confined to Anopore membranes was monitored on approaching the smectic A–isotropic transition for different lengths (carbon number n) of the aliphatic acid surfactant surface treatment attached to the cavity wall. It is clear that there are two discontinuities in $\langle \delta\nu \rangle$ as the bulk transition is approached from above. These are attributed to pretransitional smectic layering. Additionally, as the chain length n of the aliphatic surfactant decreases, the smectic layering transitions are shifted towards the bulk smectic A–isotropic transition temperature, and $\langle \delta\nu \rangle$ also decreases. The phenomenological theory behind these smectic layering transitions is currently being pursued.

Figure 5 The average quadrupole splitting frequency $\langle \delta\nu \rangle$ as a function of temperature for the liquid crystal compound 12CB- αd_2 confined to the treated channels ($C_nH_{2n+1}COOH$) of Anopore membranes. Two discontinuities in $\langle \delta\nu \rangle$ are observed for all samples before the bulk smectic A–isotropic transition temperature (vertical dotted line), which is consistent with the formation of smectic layers

6 SUMMARY

The scope of NMR for studying confined liquid crystals appears boundless. Its sensitivity to nematic director distributions of confined liquid crystals in various geometries, and to the surface-induced orientational order parameter has furthered the understanding of elasticity and pretransitional ordering. Studies of the dynamics of liquid crystals under confinement¹⁸ and liquid crystals constrained to random porous glass¹⁹ have also been very intriguing, and are attracting considerable interest. To date, the deuterium NMR technique has made the biggest impact on the fundamental understanding of confined liquid crystals, particularly in the field of PDLCs, and its role in the future looks very promising.

1 INTRODUCTION

The analytical power of the use of nematic liquid crystals as solvents in high-resolution NMR, due primarily to the pioneering work of Saupe and Englert,^{1–3} has excited a part of the NMR community since 1963. The basic phenomenon is that molecules dissolved in these ordered media are partially oriented in such a way that, while the intermolecular interactions are still averaged to zero through rapid molecular motions, all the intramolecular anisotropic interactions are no longer averaged to zero. This effect gives chemists a very powerful tool to measure, among others, shielding anisotropies, internuclear dipole–dipole interactions, quadrupolar interactions, and the anisotropic parts of the scalar coupling constants. Special emphasis must be given to the dipole–dipole interaction, because its classical relationship to molecular geometry through the well-known equation

$$D_{ij} = -\frac{h\gamma_i\gamma_j}{8\pi^2} \left\langle \frac{3\cos^2\theta - 1}{r_{ij}^3} \right\rangle \quad (1)$$

provides a very precise method of investigating the geometry of the dissolved molecules. In this equation, h is Planck's constant, D_{ij} is the dipolar coupling constant between nuclei i and j , γ_i and γ_j are their magnetogyric ratios, r_{ij} is the magnitude of the internuclear vector $\mathbf{r}_{ij}$, θ is the angle between $\mathbf{r}_{ij}$ and the magnetic field, and the angle brackets indicate the time average. Several reviews have been written on the subject,^{4–9} and readers who are not familiar with this kind of nonclassical NMR should refer to these. In spite of this great advantage, NMR studies using liquid crystal solvents have declined somewhat since the late 1970s, the reasons for which can be understood by considering the following.

Although the spectra of molecules dissolved in ordered media are much more informative than those in isotropic solvents, they are also considerably more complicated for two reasons. First, many of the residual dipolar couplings are generally much larger than the resonance frequency differences, often having values of 2 or 3 kHz. Consequently, the classical first-order approximation, which can be used when the couplings are small compared with the $\Delta\nu_i$, is no

Figure 1 ^1H NMR spectra of β -butyrolactone at 250 MHz and 20 °C: (a) Spectrum of an isotropic solution in CDCl_3 ; (b) Spectrum of an anisotropic solution in the liquid crystal solvent ZLI 1167. Many overlapping peaks are not resolved in this experimental spectrum

longer valid, even at high fields. Second, the appearance of the partially averaged dipolar couplings lifts the degeneracies among spin systems containing chemically or magnetically equivalent nuclei. Thus, for molecules dissolved in a nematic medium, one generally obtains second-order spectra that are difficult and sometimes even impossible to analyze by calculations using the spin Hamiltonian.

The complexity of this kind of nonclassical NMR is well illustrated by the spectra of β -butyrolactone shown in Figure 1. The isotropic spectrum shows a simple AMX₃ pattern, which can be easily recognized. On the other hand, the anisotropic spectrum is very complicated, and has hundreds of transitions, many of which overlap in the experimental spectrum. Such a spectrum could be analyzed, and consequently the geometric parameters derived. However, the analysis would require a good computer, some skill, and weeks of effort. The reader should be aware of the fact that if the molecule under investigation does not possess any element of symmetry and the number of spins is larger than six, its spectrum would often become impossible to calculate. Our drawers are full of spectra that we have never been able to calculate, and the situation is probably the same in many specialized laboratories around the world. Finally, perhaps the most important point is the fact that we have not found in the scientific literature a geometrical analysis of a chiral molecule through this otherwise very precise method, which allows internuclear distances to be evaluated with a precision within the amplitude of bond vibrations.

The limitations mentioned above have become a challenge, and many investigators in this field have tried to overcome them. Their basic idea is as follows: if it is possible to reduce the magnitude of the dipolar couplings to make them smaller than the frequency shift differences, or even comparable in magnitude to the isotropic part of the scalar couplings, it would be possible to convert the very strong second-order pattern

commonly shown in the spectra into a first-order spectrum analyzable by any NMR spectroscopist. It has been known from the very beginning of the NMR study of liquid crystals that this can be achieved when the director is tilted at an angle β from the magnetic field. Section 2 is devoted to showing this effect. Then it will be shown that, in some circumstances, it is possible to tilt the director from the magnetic field through sample rotation.

The first experiments on the rotation of a nematic liquid crystal around an axis perpendicular to the magnetic field were performed by the physicists Tsvetkov¹⁰ and Lippmann.¹¹ Then, Snyder¹² in 1965 and Diehl and Khetrapal¹³ in 1967 applied this old idea to the NMR study of liquid crystals. The details of the effects of this technique, which we shall refer to as the slow sample rotation experiment, were first studied by Leslie, Luckhurst, and Smith for EPR¹⁴ and by Emsley, Lindon, Luckhurst, and Shaw for applications in NMR.¹⁵ This experiment will provide us with a starting point, which will be the content of Section 3. The reason to begin our discussion with tilting the axis of rotation by 90° is not only because of the historical chronology but also because it contains all of the main ingredients to introduce the variable angle spinning technique. Unfortunately, there are two serious limitations to this approach: first, it is theoretically impossible to reduce the anisotropic interactions by more than a factor of four; second, the reduction is accompanied by an increase in linewidth, which further limits the useful reduction factor to barely one-half.

In Section 4, we shall derive the behavior of the director of a nematic when it is spun around an axis tilted at an angle β from the magnetic field, which constitutes the basis of variable angle sample spinning (VAS). The first idea of spinning nematics neither parallel nor perpendicular to the magnetic field but in between as a means to reorient the director was due to Hornreich¹⁶ in 1977, and the technique was first applied in EPR by Yo, Poupko, and Hornreich¹⁷ in 1978. The NMR applications were worked out by ourselves¹⁸ in 1981, and independently by Lippmaa et al. at Tallinn¹⁹ in 1982. Then, a detailed theoretical analysis²⁰ and a review²¹ were given shortly after the initial experimental demonstrations of VAS.

Section 5 will be devoted to the principal applications of the technique to the NMR of molecules dissolved in nematics. Applications to the NMR of liquid crystals themselves are described in *Liquid Crystalline Samples: Carbon-13 NMR*.

In the concluding Section 6, we shall try to evaluate the prospects of the VAS method for the near future, which may help the further development of one of the most fascinating aspects of NMR in chemistry, namely the structural and dynamic analysis of molecules in an anisotropic environment.

2 NMR IMPLICATIONS OF TILTING THE DIRECTOR FROM B_0

The arguments presented here are based on the assumption that the nematic sample is placed in a magnetic field of 1 T or more, so that nuclear magnetic moments are quantized along this field and that nematic director dynamics are dominated by magnetic field interactions and the mechanical motion of the sample. It will also be assumed that the rotational motions of individual molecules are fast on the NMR timescale, so that interactions can be expressed as averages.

Molecules dissolved in liquid crystals tumble rapidly but with unequal orientational probabilities, so that anisotropic intramolecular interactions are averaged to nonzero values. Only the averages of these second-rank tensorial properties in the direction of spin quantization are measurable. Quantization is along the externally applied magnetic field, which is arbitrarily defined as the laboratory z axis. We have

$$\bar{T}_{zz} = \frac{1}{3}(T_{11} + T_{22} + T_{33}) + \frac{2}{3} \sum_{\alpha,\beta} \frac{1}{2} (3 \cos \theta_\alpha^z \cos \theta_\beta^z - \delta_{\alpha\beta}) T_{\alpha\beta} \quad (2)$$

where T_{zz} , the z component of a tensorial property T , corresponds to our measure along the magnetic field. $\frac{1}{3}(T_{11} + T_{22} + T_{33})$ is the isotropic average of the interaction, often referred to as T^{iso} . The sum, which depends on the orientation through the angles

$$\theta_\alpha^z$$

between the molecular axes $(\alpha, \beta) \equiv (1, 2, 3)$ and the magnetic field, is the anisotropic part of the interaction ΔT .

In uniaxial liquid crystals such as nematics it has been shown¹² that the anisotropic part is sensitive to the angle β between the axis of orientation, the director, and the magnetic field through the simple equation

$$\bar{T}_{zz} = T^{\text{iso}} + \frac{1}{2} (3 \cos^2 \beta - 1) \Delta T \quad (3)$$

which indicates that the average property measured along the z magnetic field is made up of two terms. The first term is the invariant under the rotation of T , and the second term is the anisotropic contribution scaled by the factor $\frac{1}{2} (3 \cos^2 \beta - 1)$. In other words, this equation means that if it is possible to orient the director of a uniaxial liquid crystal at an angle β to the magnetic field then the anisotropic part of the interaction will be reduced by a factor $\frac{1}{2} (3 \cos^2 \beta - 1)$, which lies between 1 and -0.5 for $0 > \beta > \frac{1}{2}\pi$. This is true for the shielding anisotropy, the anisotropy of the scalar coupling, and for the dipolar and quadrupolar couplings that are purely anisotropic interactions.

Of course, the difficulty is that the angle β must be the same all over the sample. If this is not the case then the spectrum will not be high-resolution but a powder pattern. In other words, a homogeneous orientation is needed. This can be obtained by spinning the sample.

Having established the NMR consequences when the director is tilted from the magnetic field, we must now describe how it is possible to move the director from its equilibrium position.

3 THE SLOW SAMPLE ROTATION TECHNIQUE

3.1 Magnetic Torque Against Viscous Torque

When subjected to an external magnetic field B_0 of sufficient magnitude (usually about 0.5 T or higher), the local order directors of a nematic liquid crystal have a uniform alignment, producing a single well-defined bulk nematic director $\mathbf{n}$. This is due to the interaction between the external field and the anisotropy of the diamagnetic susceptibility, which is defined as

$$\Delta\chi = \chi_{\parallel} - \chi_{\perp} \quad (4)$$

where $\chi_{\parallel}$ and $\chi_{\perp}$ are the susceptibilities parallel and perpendicular to $\mathbf{n}$, respectively. Although $\Delta\chi$ is relatively small, the collective effect in the bulk sample is sufficient to overcome thermal disordering motions. Quantitatively, this can be expressed as a change in the potential energy P of the system:²²

$$P = -\frac{1}{3}\Delta\chi B_0^2 \frac{1}{2}(3\cos^2\beta - 1) \quad (5)$$

where β is the angle between the director and the magnetic field. For many nematics, $\Delta\chi$ is positive, so the potential energy is minimum for $\beta = 0^\circ$, and the equilibrium alignment of $\mathbf{n}$ will be along $\mathbf{B}_0$. For a few liquid crystals, most of which have no aromatic rings, $\Delta\chi$ is negative and P is minimum for $\beta = 90^\circ$; therefore, $\mathbf{n}$ will tend to be perpendicular to $\mathbf{B}_0$. Since nematics are moderately viscous fluids, the alignment of $\mathbf{n}$ is not instantaneous, but requires some time to reach equilibrium. This is governed by the competition between the viscous torque and the magnetic torque.

The potential energy gives rise to a magnetic torque τ_m on the liquid crystal director whose magnitude per unit volume is

$$\tau_m = \Delta\chi B_0^2 \cos\beta \sin\beta \quad (6)$$

According to Leslie,^{23,24} the viscous torque τ_v can be written as

$$\tau_v = \gamma_1 \dot{\beta} \quad (7)$$

where γ_1 is the Leslie rotational twist coefficient and $\dot{\beta}$ is the time rate of change of β .

The return of $\mathbf{n}$ to its equilibrium condition is related to a characteristic motional frequency expressed as ω_c , which is a function of these competing torques. Equating τ_v and τ_m in equations (6) and (7), an expression for ω_c can be obtained:

$$\gamma_1 \dot{\beta} = \Delta\chi B_0^2 \cos\beta \sin\beta \quad (8)$$

$$\dot{\beta} = \omega_c \cos\beta \sin\beta \quad (9)$$

with

$$\omega_c = \frac{\Delta\chi B_0^2}{\gamma_1} \quad (10)$$

For typical nematic liquid crystals, ω_c/B_0^2 is of the order of 4.8 Hz T^{-2} , which means that ω_c is approximately 30 Hz at 2.35 T (100 MHz proton NMR), 200 Hz at 5.87 T (250 MHz), and 1.1 kHz at 14.10 T (600 MHz).

3.2 Slow Spinning Perpendicular to the Magnetic Field

The behavior of a nematic mesophase of $\Delta\chi > 0$ being spun around an axis perpendicular to the director was first studied by Lippmann,¹¹ but it was the EPR and NMR spectra of probes dissolved in nematic phases that provided a detailed description of the director behavior.^{14,15,25-29}

The quantitative relation can be easily derived from the equality of the two torques expressed in Equation (8). According to this, at equilibrium, the director adopts an angle β relative to $\mathbf{B}_0$ given by

$$\sin 2\beta = \frac{2\gamma_1 \omega_r}{\Delta\chi B_0^2} \quad (11)$$

where $\omega_r = \dot{\beta}$ is the angular velocity of the spun sample. From equation (11), it can be seen that the maximum theoretical value for β is 45° , which is achieved when ω_r reaches a critical angular velocity that is half of the characteristic motional frequency defined in equation (10):

$$\omega_r^{\text{critical}} = \frac{\Delta\chi B_0^2}{2\gamma_1} = \frac{1}{2}\omega_c \quad (12)$$

For $\omega_r < \frac{1}{2}\omega_c$, the director will reach an equilibrium angle

$$\beta = \frac{1}{2} \sin^{-1} \left(\frac{2\omega_r}{\omega_c} \right) \quad (13)$$

When $\omega_r > \frac{1}{2}\omega_c$, it can be shown that the director rotates about the spinning axis.

3.3 Experiments and Limitations

The 94.1 MHz fluorine spectra of CF_3COOH dissolved in Phase V, obtained at various rotation speeds by Emsley and Lindon,⁶ provide a nice way to show the power and the limitations of the slow spinning technique, Figure 2. In this A_3 spin system, the line positions are determined by the F-F dipolar coupling and the electronic shielding $\sigma_F^{\text{iso}} + \Delta\sigma_F$. Compared with the static spectrum (a), the reduction of the dipolar interaction in spectrum (b) is clear, together with a shift of the central line due to the reduction of the shielding anisotropy. Unfortunately, it must also be noted that this spectrum is no longer a simple 1-2-1 triplet, and the outer lines are broadened. This effect is more pronounced in spectrum (c), where $\omega_r = \frac{1}{2}\omega_c$. Spectra (c) and (d) show clear

Figure 2 ^{19}F NMR spectra of CF_3COOH dissolved in the nematic liquid crystal Merck Phase V at 94.1 MHz, with $\omega_r(\text{critical}) = 11.8 \text{ Hz}$. The sample was rotated about an axis perpendicular to the magnetic field, and values of the rotation rate ω were (a) 0.0 Hz; (b) 9.3 Hz; (c) 11.8 Hz; (d) 14.4 Hz

evidence of being weighted sums of spectra with values of β lying in a wide range between 0° and 90° . The distribution of the values of β was first analyzed in the ESR spectra of spin probes dissolved in rotating nematic phases by Carr et al.²⁵ They showed that the results are consistent with an elliptical distribution of the angle β .

Although slow sample rotation is limited to small tilting angles of the director, where the value of the reduction factor $\frac{1}{2}(3 \cos^2 \beta - 1)$ is not very different from unity, this technique has been used by Emsley and Lindon^{27,28} to separate the anisotropic from the isotropic interactions, such as J^{iso} from D , or σ^{iso} from $\Delta\sigma$. However, the original goal, which is to reduce the dipolar interaction to such an extent that a first-order spectrum can be obtained, cannot be reached by this method. On the other hand, the beauty of the VAS technique, which we are going to describe in the next section, is to actually narrow the lines as the tilt angle between the magnetic field and the director increases. Because the slow sample rotation technique was discovered first, and all the necessary theoretical backgrounds have been discussed, the equations developed in this section will be found useful below.

4 SPINNING AT VARIOUS ANGLES

The work on slow spinning samples was done very early—most probably because many of the experiments were performed on conventional spectrometers with electromagnets, in which the probes are designed to spin the samples about an axis perpendicular to B_0 . There is another well-known situation in these electromagnets, namely the case of nematics with negative $\Delta\chi$. These orient spontaneously with the director perpendicular to the magnetic field. In this case, it is commonly said that rotation does not affect the orientation of a nematic; but this is not true. If the sample is kept static in the field, the directors distribute in a plane perpendicular to B_0 . When the sample is rotated, the directors reorient about the unique rotation axis, which remains perpendicular to B_0 . This, of course, would not change the NMR measurement, but the interesting point is that the difference of the director behavior between the two cases indicates the roles of B_0 , $\Delta\chi$, and the rotation axis in this problem.

In the following discussion, the derivation of Hornreich¹⁶ together with that of Courtieu et al.²⁰ are followed.

4.1 Average Potential Theory

If the liquid crystal were spun around an axis tilted from B_0 by an angle β at an angular velocity larger than ω_c , the director would not have time to orient parallel to the field, but would orient in such a way that the average of the potential energy over one cycle of the rotation is minimum. This average potential energy $\bar{P}$ is obtained from Equation (5) by averaging $\cos^2 \beta$ over one cycle of the rotation. To calculate the average of $\cos^2 \beta$, consider a reference frame fixed relative to the bulk of the liquid crystal, with the polar axis along the spinning axis as shown in Figure 3. Here we denote the principal axis of the bulk liquid crystal as R , which will be defined as the spinning axis later.

Assume that the director is stationary relative to the bulk liquid and is described by a polar angle δ and an azimuthal

Figure 3 Definition of the axes and angles used in the text: B_0 , n , and R are the magnetic field, the director, and the spinning axis, respectively; β is the angle between B_0 and n , η is that between B_0 and R , and δ is that between n and R

angle ϕ . Since the angle between the spinning axis and the magnetic field is η , in this frame the magnetic field has a constant polar angle η and a constantly changing azimuthal angle $\phi_m = \omega_r t$. The cosine of the angle β between the director and the magnetic field is

$$\cos \beta = \cos \eta \cos \delta + \sin \eta \sin \delta \cos(\phi_m - \phi) \quad (14)$$

The average of $\cos^2 \beta$ over one cycle of the rotation is

$$\cos^2 \beta = \cos^2 \eta \cos^2 \delta + \frac{1}{2} \sin^2 \eta \sin^2 \delta \quad (15)$$

Inserting this into Equation (5) and simplifying the result, the average potential energy is obtained:

$$\begin{aligned} \bar{P} &= -\frac{1}{3} \Delta\chi B_0^2 \left[\frac{1}{2} (3 \cos^2 \eta - 1) \right] \left[\frac{1}{2} (3 \cos^2 \delta - 1) \right] \\ &= \frac{1}{3} \Delta\chi B_0^2 f(\eta, \delta) \end{aligned} \quad (16)$$

The angular part of the function $f(\eta, \delta)$ is plotted in Figure 4 for different values of η . Defining the magic angle as $\theta_m = \arccos(\frac{1}{3})^{1/2} = 54^\circ 44'$, it can be analyzed in the following way for $0^\circ \leq \eta \leq 90^\circ$.

1. For nematics with $\Delta\chi > 0$, (a) when $\eta < \theta_m$, the potential energy is minimum at $\delta = 0^\circ$, and the director tends to align along the rotation axis; (b) when $\eta = \theta_m$, the potential energy is independent of δ , which means that the director has no preferred orientation; (c) when $\eta > \theta_m$, the potential energy is minimum at $\delta = 90^\circ$, and the director is distributed in a plane perpendicular to the rotation axis.
2. For nematics with $\Delta\chi < 0$, the situation of the minimum potential changes so that, (a) when $\eta < \theta_m$, the director is distributed in a plane perpendicular to the rotation axis; (b) when $\eta = \theta_m$, the director does not show a preferred orientation; (c) when $\eta > \theta_m$, the director aligns along the rotation axis.

The average potential treatment presented above is semi-quantitative, and holds only for high spinning speed. However, it does give a simple understanding of the phenomenon. A complete mechanistic analysis been given by Hornreich¹⁶ and by Courtieu et al.²⁰ It leads to the conclusion that the theoretical situation described in Sections 2 and 3 can be achieved through sample spinning at an angular frequency five or more

Figure 4 Plot of the function $f(\eta, \delta) = -\frac{1}{4}(3 \cos^2 \eta - 1)(3 \cos^2 \delta - 1)$

time the critical spinning rate. In this situation, the angle β reaches a steady-state position where the director is homogeneously aligned on the rotation axis, $\beta \approx \eta$, as long as we are inside the region of stability. The latter depends only on the sign of the diamagnetic susceptibility anisotropy. The next section will be devoted to the experimental confirmation of the above derivation using NMR.

5 APPLICATION OF VAS TO THE NMR OF DISSOLVED MOLECULES

In this section, we shall show some examples of the application of VAS to study the NMR of small molecules dissolved in nematic solvents. The basis of these applications is the ability of VAS to reduce various anisotropic interactions by a factor of $\frac{1}{2}(3 \cos^2 \beta - 1)$, as expressed by Equation (3). Actually, the tremendous advantage of the VAS technique in reducing H–H dipolar couplings has found another important application in the simplification of the ^1H and ^{13}C spectra of liquid crystals (see *Liquid Crystalline Samples: Carbon-13 NMR*).

5.1 Practical Considerations for VAS

We have seen in Section 4 that in VAS, the orientation of the nematic director is dependent on the spinning angle η , the spinning rate, and the magnetic anisotropy $\Delta\chi$. When the spinning rate is fast, for a liquid crystal with $\Delta\chi > 0$, the director orients along the spinning axis for $0^\circ < \eta < \theta_m = 54^\circ 44'$, lies around a cone about the spinning axis for η near the magic angle, and is distributed perpendicular to the spinning axis for $\theta_m < \eta < 90^\circ$. The situation is opposite for a liquid crystal with $\Delta\chi < 0$. However, when the spinning angle is near θ_m , the situation is more complicated. For example, for a nematic liquid crystal with $\Delta\chi < 0$, the director orients perpendicular to the spinning axis when η is between 0° and 52° , but lies around a cone in the vicinity of the magic angle, and spinning sidebands become a prominent feature of the spectra.²⁹ The patterns and intensities of the sidebands depend upon the dipolar interactions and frequency shifts of the system as well as the spinning rate and spinning angle. A study of these effects was made by studying the ^{19}F spectra of $\text{CF}_2\text{ClCCl}_3$ in two liquid crystal solvents (Merck ZLI 2334, $\Delta\chi > 0$; ZLI 1167, $\Delta\chi < 0$). The details of the theoretical analysis will not be repeated here; it is sufficient to say that the results agree quite well with the experimental data.

The spinning sidebands are, of course, not desirable in most applications of the VAS method. Fortunately, they can be avoided and even totally eliminated by setting the spinning rate fast enough and the angle η far away enough from the magic angle. In the experiments described in the rest of this section, the conditions were such that the fast spinning limit is reached. However, other complications would appear at very high spinning rates, where inertial forces become important.²¹

5.2 Reduction of Dipolar Interactions

The original goal of the VAS technique was to reduce the dipolar interaction and change second-order spectra into first-order ones. This goal was successfully reached,²⁰ and the result is illustrated in Figure 5, which shows the change in the ^{19}F spectra of $\text{CF}_2=\text{CFBr}$ dissolved in a nematic solvent. When the sample is stationary or spun at $\eta = 0^\circ$, the spectrum is of the ABC type, because the D_{ij} values are of the same order of magnitude as the frequency shifts. Tilting the spinning axis reduces D_{ij} more than the frequency shift differences, and the second-order spectrum gradually changes into a first-order one when η increases. At $\eta = 51^\circ$, the ABC pattern is converted

Figure 5 ^{19}F NMR spectra of $\text{CF}_2=\text{CFBr}$ dissolved in the nematic liquid crystal *p*-*n*-pentylphenyl 2-chloro-4-(*p*-*n*-pentylbenzoyloxy)benzoate at 75.25 MHz and 31°C . The spinning rate was 75 Hz, and values of the spinning angle η are indicated in the spectra

into an AMX pattern, from which the values of the couplings can be obtained directly. An analysis of the spectra yields the relative signs of D_{ij} and J_{ij} . In the limit of $\eta = \theta_m$, only the isotropic scalar couplings remain, and the centers of the multiplets give the isotropic shielding in the liquid crystal solvent.

A reduction of the dipolar coupling constants, of course, also simplifies the ^1H spectrum of solute molecules in liquid crystal solvents. For example, the ^1H spectrum of norbornadiene, an eight-spin system, is quite complicated and difficult to analyze, but it becomes essentially first-order when the system is spun at $\eta = 45.2^\circ$.³⁰ Some peaks in the VAS spectrum overlap with each other because the order parameters are quite small, but the three largest coupling constants can be immediately obtained from the spectrum with VAS. From these data, very good initial estimates of the order parameters were made to aid the analysis of the complicated spectrum for $\eta = 0^\circ$. A simplification of the spectra of thiophene dissolved in two nematic solvents, one with $\Delta\chi > 0$, and the other with $\Delta\chi < 0$, was also observed.³¹ The proton dipolar coupling constants of these systems were measured, and it was confirmed that in both cases, the coupling constants are scaled by the angular factor predicted by the theory discussed in the previous section.

In a VAS experiment, it is essential to determine the angle η between the spinning axis and the magnetic field accurately. The determination can be made by the use of an optical pointer.³² Another way of determining η is to take advantage of the reduction in the dipolar coupling constant by comparing the dipolar splittings of a solute molecule with and without sample spinning. If the director of the liquid crystalline solvent aligns along the spinning axis, the ratio between the dipolar splittings in the two cases is $\frac{1}{2}(3 \cos^2 \eta - 1)$; if it aligns perpendicularly to the spinning axis, the factor is $-\frac{1}{4}(3 \cos^2 \eta - 1)$. The ^1H signal of CH_2Cl_2 ,³³ the ^{19}F signal of $\text{CF}_2\text{ClCCl}_3$,³⁴ and the ^{13}C signals of CH_2I_2 ²⁰ and CHCl_3 ³⁵ have been used for this purpose.

5.3 Shielding Anisotropy

The use of liquid crystals as solvents to determine the shielding anisotropy of solute molecules is a well-known method³⁶ (see *Anisotropy of Shielding and Coupling in Liquid Crystalline Solutions*). The principle of the technique is to follow the resonance frequencies of the solute as its molecular orientation changes. This change can be induced by several methods, including changes of phase, solute concentration, or temperature. However, each has its own disadvantage, leading to various uncertainties in the results.³⁶ On the other hand, the VAS method does not require any internal change in the system itself, and may avoid some of these problems.

Väänänen et al. have demonstrated the use of the VAS technique to determine the shielding anisotropy in CH_3I .³² To do this, it should be recalled that Equation (3) is applicable to both the dipolar coupling constant and the shielding anisotropy. By taking the ratio of these two kinds of interactions, the factor $\frac{1}{2}(3 \cos^2 \beta - 1)$ can be eliminated to give

$$\sigma^{\text{exp}} = \sigma^{\text{iso}} + \frac{2}{3} \Delta\sigma_{\text{H}} S_{zz} \frac{D_{\text{HH}}^{\eta}}{D_{\text{HH}}^0} \quad (17)$$

where σ^{exp} is the experimental electronic shielding. Then, the shielding anisotropy $\Delta\sigma_{\text{H}}$ was obtained from the slope of the

plot of σ^{exp} versus the observed dipolar coupling constant D_{HH}^{η} as the angle was varied gradually. Using this approach, it was found that $\Delta\sigma_{\text{H}}$ was dependent on the liquid crystal solvent, which could be caused by the anisotropy of the local effects on σ^{exp} and different deformational effects of the liquid crystal solvents on the methyl groups of methyl iodide and the reference molecule, tetramethylsilane. This observation confirms similar results reported earlier that both the ^1H and the ^{13}C shielding anisotropies of CH_3CN are dependent on the liquid crystal solvent, and that they are linearly related to each other.³⁷

5.4 Quadrupolar Interactions

When VAS is used to cause the nematic director to align along an axis forming an angle β with respect to $\mathbf{B}_0$, the quadrupolar interaction is also scaled by a factor of $\frac{1}{2}(3 \cos^2 \beta - 1)$. This causes the NMR peaks of quadrupolar nuclei to be much sharper and the splittings to be less. Taking advantage of this effect and following the example of an earlier study by proton NMR,³⁸ Kumar et al.^{39,40} used deuteriochloroform as a probe to investigate the effect of very small $\Delta\chi$, which was reached by mixing liquid crystals with positive and negative values of $\Delta\chi$ in proper ratios, on the orientation of the nematic directors in VAS experiments. To do this, they measured the deuterium NMR spectra of CDCl_3 in several mixtures of liquid crystals with different values of $\Delta\chi$. Their results show that, for a liquid crystal with a positive $\Delta\chi$ spinning along an axis with $\beta < 54^\circ 44'$, the director orients parallel to the spinning axis above a critical spinning rate, as discussed in the previous section. However, for a system with nearly zero but positive $\Delta\chi$, the nematic director orients along the spinning axis at low spinning speeds, but orients perpendicularly to the spinning axis at high speeds, for $\beta < \theta_m = 54^\circ 44'$. For a system with a very small but negative value of $\Delta\chi$, the behavior is similar for $\eta > 54^\circ 44'$, but no change in the director orientation with spinning speed was observed for $\beta < 54^\circ 44'$, but some spinning sidebands were observed indicating director reorientation.

A rather different application of VAS to deuterium NMR is the study of side-chain nematic liquid crystal polymers.^{41,42} Because these polymers have very high rotational viscosities, ω_c is of the order of 0.001–0.1 Hz at $B_0 = 7.1\text{ T}$ [see Equation (10)], so that very slow spinning was used to study the systems. However, it takes these liquid crystal polymers a very long time to reach equilibrium because of their high viscosities. Therefore, the initial stage of the time dependence of the deuterium NMR spectra were investigated, using synchronized data acquisition with the sample rotation. The kinetic results were used to measure the rotation viscosities⁴¹ and study the convection director structures.⁴²

5.5 Two-Dimensional NMR with VAS

Two-dimensional NMR of solute molecules in liquid crystal solvents has not enjoyed the success of that for isotropic solutions. This is mainly because the large dipolar interactions make the spectra second order, so that correlation relations, which are the essential features in 2D NMR, are usually not very informative. This problem can be overcome partly by symmetry filtering,^{43–45} but the scope is still rather limited.

On the other hand, because the VAS method can simplify a second-order spectrum into a first-order one, it has a potential application in the 2D NMR of liquid crystal solutions.

As an example of this application, the ^{19}F spin echo spectra of the chiral molecule $\text{CF}_3\text{CFBrCF}_2\text{Br}$ dissolved in a liquid crystal with a negative $\Delta\chi$ (Merck ZLI 2806) was studied.²¹ The normal 1D spectrum is a complicated ABC_3X type and very difficult to analyze, and the 2D spin echo spectrum is practically impossible to interpret. However, the spectrum turned into an ABM_3X type when the sample was spun at $\eta = 63.9^\circ$ or 58.4° .⁴⁶ The 2D spin echo spectra can be regarded as first-order D -resolved spectra, where the residual dipolar couplings appear in the ω_1 dimension, and the resonance frequencies in the ω_2 dimension. The analysis of the spectra in the ω_1 dimension then yielded the values of D_{ij} for this chiral molecule.

6 PERSPECTIVES

The most important characteristic of liquid crystals is the presence of orientational ordering without long-range positional ordering. Various kinds of anisotropic interactions, including dipolar couplings, quadrupolar couplings, and electronic shielding, can be used to study the orientational ordering and dynamics of liquid crystals, as well as the structures and motions of solute molecules. However, these interactions are often so large that the NMR spectra are either too broad or too complicated to be tractable. When liquid crystals are spun at high speeds along the magic angle, the NMR linewidths can be greatly reduced, just like those for solids, but information on anisotropic interactions is lost. On the other hands, the use of VAS can reduce the anisotropic interactions to yield simplified spectra, and in the mean time preserve the valuable anisotropic interactions, which are scaled by a proper factor. Solute spectra are greatly simplified, and the linewidths of bulk liquid crystals are reduced, bringing important advantages for the spectral analysis. So far, the potential of using VAS for the structural determination of complex solute molecules has not been fully realized, but investigations of the order parameters of various types of liquid crystals have been very successful.

It must be pointed out again that the reduction of the anisotropic interactions in liquid crystals by VAS is not a time-averaging effect as in MAS experiments for solids, but an effect of the alignment of the director. Therefore, a fundamental requirement for VAS experiments to be effective is the presence of macroscopic ordering of the liquid crystal director along the magnetic field in a static situation. This situation is fulfilled for nematic liquid crystals at $B_0 > 0.5\text{ T}$, and for smectics that can be aligned through cooling from the nematic phase. However, for cholesterics and chiral smectics that have short pitches, and for smectics that have no or very short nematic ranges, powder patterns are often obtained, and the VAS technique is not very useful. In these cases, deuterium NMR without sample spinning is most advantageous. (See *Liquid Crystalline Samples: Deuterium NMR*).

1 INTRODUCTION

As a result of Brownian motion in liquids, not only are the direction-dependent properties of chemical shift and indirect dipole–dipole coupling lost, and only one-third of the traces of the respective tensors observed, but also the direct dipole–dipole coupling as well as the quadrupolar coupling are averaged to zero, so that these interactions can only contribute to relaxation. In particular, the loss of direct dipolar coupling is very serious, because it has a quite simple geometrical meaning in that it depends upon the inverse cube of the internuclear distance, the degree of orientation of the internuclear axis with respect to the applied magnetic field, and the product of the gyromagnetic ratios of the interacting nuclei. In solids that are ‘fully oriented’, the direct coupling was, of course, observed in the 1950s; however the large number of interacting spins led to very complex spectra, with broad features, resulting in low accuracy of information on internuclear distances.

NMR spectroscopists have always been aware of this missing information in liquid samples, and have repeatedly tried to produce partially oriented systems by various means. But only in 1963, when Saupe and Englert¹ used liquid crystals as solvents, were the first highly resolved spectra showing direct dipolar coupling observed. The main idea of this approach was that in liquid crystal solvents the solute molecules still rotate and diffuse as in normal liquids, but, owing to their interaction with the anisotropic solvent, they are partially oriented. The diffusion and rotation are responsible for the averaging out of intermolecular direct dipolar coupling, i.e., we observe the ‘isolated’ spin system of one solute molecule, and the liquid crystal, which in the magnetic field is uniaxially oriented, keeps the solute molecular axes partially

parallel (i.e., oriented), causing the average dipolar coupling to deviate from zero. Since the motion of the solute molecules does not deviate appreciably from that of normal liquids, the relaxation times of partially oriented molecules are similar to those of the liquid. Therefore linewidths of the order of 1 Hz can be obtained, and dipolar couplings (i.e., molecular structure) can be measured with considerable accuracy.^{2–11}

This method of structure determination is relatively fast compared with other approaches such as microwave spectroscopy, which usually needs spectra of several isotopically substituted species, and furthermore only allows one to study dipolar molecules, or electron diffraction, which determines the position of light nuclei such as protons with low accuracy and furthermore has difficulties in discriminating between similar interatomic distances. NMR of oriented molecules, on the other hand, has the limitation that coupling to quadrupolar nuclei except ²D is rarely observed, because it is fully or partially averaged out by quadrupolar relaxation.

2 LIQUID CRYSTALS AS SOLVENTS

The liquid crystals used as orienting solvents consist of nonspherical, either rod- or disk-shaped, molecules that below a certain transition temperature are partially oriented owing to attractive dispersive—as well as repulsive—interactions. In spite of their orientation, they have liquid-like properties such as diffusion and flow.

Of the three main types of liquid crystals—nematic, smectic, and cholesteric—it is mainly the nematic phases, which have long-range order in the molecular axes but not in the centers of gravity, and the smectic phases, which have order in both, that are used in practice (see Figure 1). They may be pure compounds (thermotropics) or mixtures of various compounds (lyotropics). The latter contain molecules with hydrophobic paraffin chains and hydrophilic headgroups as well as water.

The most important compounds are the thermotropic azo-, azoxy-, and azine-type molecules, biphenyls, phenylcyclohexanes or bicyclohexanes, and lyotropic mixtures of alkyl sulfates, alcohols, sodium phosphate, and water.

Liquid crystal solvents are uniaxially oriented by the applied magnetic field (>0.1 T) or by electric fields. The reason is the diamagnetic or dielectric anisotropy of the molecular aggregates. The axis of largest diamagnetic susceptibility is oriented perpendicularly to the magnetic field.

Molecular solutes in the liquid crystal solvent are also oriented. The degree of order is usually smaller than 0.1, and depends upon the concentration of the solute and the temperature (roughly 1% change K^{−1}). Obviously, in order to obtain small linewidths of the spectra, concentration and temperature gradients must be avoided.

Because many liquid crystals contain aromatic rings with large diamagnetic susceptibilities perpendicular to the ring plane, usually the optic axis of the liquid crystal is oriented along the magnetic field; exceptions are cyclohexane ring-containing compounds.

The orientation of smectic liquid crystals is quite slow, and consequently stable, so that probes at arbitrary angles between the optical axis and the magnetic field may be studied. In contrast the orientation of nematic liquid crystals is fast.

Figure 1 Schematic representation of liquid crystal phases in a magnetic field: (a) thermotropic nematic; (b) thermotropic smectic; (c) lamellar lyotropic with water layers, ionic hydrophilic head groups, and hydrophobic tail paraffin chains

3 DEGREE OF ORDER OF THE SOLUTE

Molecules dissolved in liquid crystals are oriented because of their interaction with the anisotropic solvent. The degree of order may be described by the order tensor $\mathbf{S}$:¹²

$$S_{pq} = \frac{1}{2} (3 \cos \Theta_{pz} \cos \Theta_{qz} - \delta_{pq}) \quad (1)$$

where Θ_{pz} is the angle between the liquid crystal optical axis and the p axis in a molecule-fixed coordinate system. δ_{pq} is the Kronecker delta, and the z axis is parallel to the optical axis.

$\mathbf{S}$ is a traceless symmetric tensor with five independent elements. Solute symmetry reduces the number of elements required for a description of order. A plane of symmetry (x, y) is fully characterized by the elements S_{xx} , S_{yy} and S_{xy} . If there is also a C_2 axis (y) then S_{xx} and S_{yy} define the order. An n -fold axis of symmetry (y) reduces the necessary $\mathbf{S}$ components to S_{yy} , which is equal to $-2S_{xx} = -2S_{zz}$. For S values reported in the literature, it is usually assumed that the liquid crystal optical axis is parallel to the applied field. If the axis is at an angle of β with respect to the field then the measured S also contains a factor of $\frac{1}{2}(3 \cos^2 \beta - 1)$.

The degree of order of any axis ij in a molecule without symmetry can be derived from the $\mathbf{S}$ components in the molecular axis system (x, y, z):

$$\begin{aligned} S_{ij} &= \sum_{p,q} \cos \Theta_{ijp} \cos \Theta_{ijq} S_{pq} \\ &= \frac{1}{2} S_{zz} (3 \cos^2 \Theta_{ijz} - 1) + \frac{1}{2} (S_{xx} - S_{yy}) (\cos^2 \Theta_{ijx} - \cos^2 \Theta_{ijy}) \\ &\quad + 2S_{xy} \cos \Theta_{ijx} \cos \Theta_{ijy} + 2S_{xz} \cos \Theta_{ijx} \cos \Theta_{ijz} \\ &\quad + 2S_{yz} \cos \Theta_{ijy} \cos \Theta_{ijz} \end{aligned} \quad (2)$$

In analogy with the fact that two nuclei whose internuclear axis makes an angle of $54^\circ 44'$ (the magic angle) with the applied magnetic field have zero direct dipolar coupling, there exists in every molecule a continuum of directions that have a degree of order of zero; i.e., nuclei whose connecting axis lies on this continuum have no dipolar interaction. The continuum consists of a double cone that, for molecules with two planes of symmetry, cuts the planes at directions $x/y = \pm (-S_{yy}/S_{xx})^{1/2}$. Consequently, if the two degrees of order of the

plane have different signs then there is a direction in the plane in which two nuclei will not interact. On neighboring axes, the interaction is small, i.e., the structure information is of poor quality because of the relative uncertainties of the necessary corrections for vibrations and for deformation. (See Sections 9.2.1 and 9.2.2.)

In principle, a priori, there is no information available on the magnitude of molecular S values nor on the interdependence between molecular structure and order parameters. There is, however, a possibility to gain some insight if the assumptions of the deformation theory¹³ (see Section 9.2.2) are used.

For a planar molecule (x, y), the segment n (bond or larger structure) makes the following contributions to the molecular interaction tensor $\mathbf{A}$, which determines the orientation:

$$\left. \begin{aligned} A_{xx}^n &= \Delta A_n \left[\frac{2}{3} - (1 - \frac{1}{3} \eta_n) \sin^2 \Theta_n \right] \\ A_{yy}^n &= \Delta A_n \left[\frac{2}{3} - (1 - \frac{1}{3} \eta_n) \cos^2 \Theta_n \right] \\ A_{zz}^n &= -\frac{1}{3} \Delta A_n (1 + \eta_n) \\ A_{xy}^n &= \frac{1}{2} \Delta A_n (1 - \frac{1}{3} \eta_n) \sin 2\Theta_n \\ A_{xz}^n &= A_{yz}^n = 0 \end{aligned} \right\} \quad (3)$$

Here the z axis is perpendicular to the plane and Θ_n is the angle between the bond axis and the molecular x axis. The degrees of order may be obtained by integration as described in Section 9.2.2.

As an example, in benzene, the relation between the ordering matrix

$$S_{\alpha\beta} = S \begin{bmatrix} -\frac{1}{2} & 0 & 0 \\ 0 & -\frac{1}{2} & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad (4)$$

and the interaction parameters is

$$\begin{aligned} A_{xx} &= A_{yy} = -\frac{1}{2} A_{zz} = \Delta A_{CC} (1 + \eta_{CC}) + \Delta A_{CH} (1 + \eta_{CH}) \\ &= -\frac{2}{9} ck_B T = U_{\text{ext}} \end{aligned} \quad (5)$$

with

$$S_{zz} = \frac{3}{4c} \left[e^c \left(\int_0^1 e^{cx^2} dx \right)^{-1} - 1 \right] - \frac{1}{2} \quad (6)$$

Here ΔA is the anisotropy and η_A the asymmetry of the interaction tensor $\mathbf{A}$, and U_{ext} is the orienting potential energy; k_B is Boltzmann's constant. For benzene, the η s are small or zero, but the Δ As vary considerably with the liquid crystal solvent. ΔA_{CC} is in the range $(12-18) \times 10^{-22}$ J and ΔA_{CH} varies between -4×10^{-22} and $+7 \times 10^{-22}$ J. The change of sign indicates a change of the preferred orientation of the bond parallel (+) or perpendicular to the liquid crystal axis.

For the addition of Δ As, bonds may be shifted to any position, as long as they retain their orientation. 1,2- and 1,3-disubstituted benzenes with equal substituents should have the same degrees of order (with exchanged C_2 axes). This is only approximately fulfilled, indicating the limitations of the approach.

4 DIRECT DIPOLAR COUPLING AND MOLECULAR GEOMETRY

The direct dipolar coupling is defined as follows:

$$D_{ij} = -K_{ij} S_{ij} / r_{ij}^3 \quad (7)$$

where

$$K_{ij} = -\mu_0 \hbar \gamma_i \gamma_j / 8\pi^2 \quad (8)$$

depends upon the gyromagnetic ratios of the nuclei i and j .

K_{ij} may be split into the individual nuclear contributions $K_{ij} = k_i k_j$. For $S_{ij} = 1$ and $r_{ij} = 0.1$ nm, the k s as well as the K_{ij} are summarized in Table 1.

For partially oriented solutes, the degree of order is normally of the order of 0.1, and internuclear distances are larger than 100 pm, so that the direct couplings will not usually exceed 3 kHz.

As equation (7) demonstrates, each direct coupling contains two unknown parameters, r_{ij} and S_{ij} , which cannot be determined separately. Also, in systems of several nuclei for which a network of direct couplings has been measured, it is only possible to determine distance ratios but not absolute distances unless a reference absolute distance determined by a different spectroscopy has been introduced. The reference length will then determine all the absolute distances as well as the S values.

For simple spin systems, the relations between the molecular geometry and the direct couplings can be represented analytically. An almost trivial case is benzene, for which the

distance ratios r_o/r_p and r_m/r_p in the proton hexagon of $\frac{1}{2}$ and $\frac{1}{2}\sqrt{3}$ lead to ratios of direct couplings $D_o/D_p = 2^3$ and $D_m/D_p = (2/\sqrt{3})^3$. Real structural information can only be derived if the couplings from the protons to a carbon (^{13}C) are also observed. One structural parameter, $r_{\text{CH}}/r_{\text{HH}}^0$, fully determines the problem.

For a methyl group, the following equation is valid:

$$\frac{D_{\text{CH}}}{D_{\text{HH}}} = \frac{\gamma_{\text{C}}}{\gamma_{\text{H}}} \left(\frac{r_{\text{HH}}}{r_{\text{CH}}} \right)^3 \left[\left(\frac{r_{\text{HH}}}{r_{\text{CH}}} \right)^2 - 2 \right] \quad (9)$$

which determines the distance ratio from the measured direct coupling ratio. The angle β between the C_3 axis and the CH bond is obtained from

$$\sin \beta = 3^{-1/2} r_{\text{HH}} / r_{\text{CH}} \quad (10)$$

The relation for a rectangular system of four nuclei,¹⁴

$$\frac{D_{12}}{D_{23}} \left(\frac{r_{12}}{r_{23}} \right)^5 - \frac{D_{13}}{D_{23}} \left[1 + \left(\frac{r_{12}}{r_{23}} \right)^2 \right]^{5/2} + 1 = 0 \quad (11)$$

shows that, with an increasing number of nuclei, the help of computers for a solution of the equation is necessary. On the other hand, such relations are of interest, because they allow the discussion of the uniqueness of solutions as well as the possible accuracy of the geometrical information obtained. So, for instance, the shape of the rectangle has two solutions for $|D_{12}| > |D_{13}| < |D_{23}|$, and only one solution for $|D_{12}| < |D_{13}| < |D_{23}|$. The situation is particularly difficult if, by coincidence, the relation $D_{13}/D_{23} = |D_{12}/D_{23}|[(D_{12}/D_{23})^{2/3} + 1]^{-3/2}$ is fulfilled, because then, depending upon small errors in the D s, there exist two very similar, one, or no solutions.

In general, therefore, it is recommended to record several spectra in different solvents, which preferably have different ratios of S values. The latter condition reduces the errors in a combined fit.

The number of different D couplings in a system of n nuclei without symmetry is equal to $\frac{1}{2}n(n-1)$. These couplings must define the five S values as well as the $3(n-2)$ coordinates of the spin system (six coordinates define an absolute distance as a basis). In order to have a fully determined system, the following relation must be fulfilled:

$$\frac{1}{2}n(n-1) - 5 - 3(n-2) \geq 0, \quad \text{i.e., } n \geq 7 \quad (12)$$

By similar arguments, it can be shown that in planar molecules without symmetry, $n \geq 5$, and with C_2 symmetry, the condition is $n \geq 4$. There are two ways out of the difficulty if a system is underdetermined. Either several spectra are combined, which is only recommended if the solvent effects on the structure (deformation—see Section 9.2.2) are corrected, or the number of couplings is increased by also considering ^{13}C information, i.e., satellite spectra of protons or ^{13}C spectra.¹⁵ In the latter case, the information content of subsystems corresponding to ^{13}C in a particular position must be analyzed separately; some may be overdetermined or just determined, while simultaneously others can be underdetermined.

Table 1 Relative Size of Direct Dipolar Couplings K_{ij} for $S_{ij} = 1$ and $r_{ij} = 0.1$ nm and Nuclear Contribution Factors k_i ($K_{ij} = k_i k_j$)

5 SPECTRA OF ORIENTED SPIN SYSTEMS

5.1 Experimental Details

Preparation of samples is relatively simple. Approximately 10 mol% of the solute is brought into the liquid crystal solvent, which has been heated in the NMR sample tube to the isotropic range. Care is taken to mix thoroughly the components in order to avoid concentration gradients, which, via the concentration dependence of the S value, would produce considerable line broadening in the wings of the spectral range. Temperature gradients can be reduced by using double walled sample tubes with, for example, D₂O, in the interwall space. This liquid, which can also be used as a locking substance provides faster convection than the viscous liquid crystal in the inner tube.

Smectic samples must be cooled from the isotropic state in the magnetic field in order to produce homogeneous orientation, whereas nematic samples orient easily and rapidly after being brought into the field. Nematic samples can be rotated in the field of superconducting magnets in order to average out field gradients. The spectral width is usually several kilohertz, and a good signal-to-noise ratio for ¹H is reached with 1–10² FIDs. If ¹³C satellites at natural abundance are studied, 10²–10⁴ FIDs are required. For ¹³C spectra at natural abundance, the relative receptivity of the nucleus (2×10^{-4}) with respect to the protons considerably increases the measuring time.

5.2 Theory

NMR spectra of molecules partially oriented in liquid crystal solvents are, for nuclei with $I = \frac{1}{2}$, characterized by the following Hamiltonian (in frequency units):

$$\hat{\mathcal{H}} = -(2\pi)^{-1} \sum_i \gamma_i \hat{\mathbf{I}}_i \cdot (\mathbf{1} - \sigma_i) \cdot \mathbf{B} + \sum_{i < j} \hat{\mathbf{I}}_i \cdot \mathbf{T}_{ij} \cdot \hat{\mathbf{I}}_j \quad (13)$$

where $\mathbf{B}$ is the applied magnetic field in the z direction, γ_i is the gyromagnetic ratio of nucleus i , and the general coupling tensor $\mathbf{T}_{ij} = \mathbf{J}_{ij} + 2\mathbf{D}_{ij}$. Neglecting terms that do not commute with the total spin components in the z direction, we obtain

$$\begin{aligned} \hat{\mathcal{H}} = & -(2\pi)^{-1} \sum_i \gamma_i \hat{I}_{iz} (1 - \sigma_{iz}) B_z \\ & + \sum_{i < j} [T_{ijzz} \hat{I}_{iz} \hat{I}_{jz} + \frac{1}{4} (T_{ijxx} + T_{ijyy}) (\hat{I}_{i+} \hat{I}_{j-} + \hat{I}_{i-} \hat{I}_{j+}) \\ & + \frac{i}{4} (T_{ijxy} + T_{ijyx}) (\hat{I}_{i+} \hat{I}_{j-} - \hat{I}_{i-} \hat{I}_{j+})] \end{aligned} \quad (14)$$

where $\hat{I}_{+}$ and $\hat{I}_{-}$ are the raising and lowering operators, respectively.

Averaged over the anisotropic tumbling motion, we find in a laboratory-fixed coordinate system (x', y', z'),

$$\langle T_{x'x'} \rangle = \langle T_{y'y'} \rangle = \frac{3}{2} T^{\text{iso}} - \frac{1}{2} \langle T_{z'z'} \rangle \quad (15)$$

where

$$T^{\text{iso}} = \frac{1}{3} (T_{x'x'} + T_{y'y'} + T_{z'z'}) \quad (16)$$

$$\langle T_{z'z'} \rangle = T^{\text{iso}} + T'^{\text{aniso}} \quad (17)$$

with

$$T'^{\text{aniso}} = \frac{2}{3} \sum_{\alpha, \beta} S_{\alpha\beta} T_{\alpha\beta} \quad (18)$$

$$S_{\alpha\beta} = \frac{1}{2} (3 \cos \Theta_{\alpha z'} \cos \Theta_{\beta z'} - \delta_{\alpha\beta}) \quad (19)$$

Transformed to a molecule-fixed system (x, y, z), we have

$$\langle T_{ab} \rangle = (T^{\text{iso}} - \frac{1}{2} T'^{\text{aniso}}) \delta_{ab} + \frac{3}{2} T'^{\text{aniso}} \cos \Theta_{z'a} \cos \Theta_{z'b} \quad (20)$$

$$T^{\text{aniso}} = \frac{1}{2} (3 \cos^2 \alpha - 1) T'^{\text{aniso}} \quad (21)$$

where α is the angle between the optical axis of the liquid crystal and the magnetic field.

Finally, the effective Hamiltonian is

$$\begin{aligned} \hat{\mathcal{H}} = & -(2\pi)^{-1} \sum_i \gamma_i \hat{I}_{iz} (1 - \sigma_i^{\text{iso}} - \sigma_i^{\text{aniso}}) B_z \\ & + \sum_{i < j} \{ T_{ij}^{\text{iso}} [\hat{I}_{iz} \hat{I}_{jz} + \frac{1}{2} (\hat{I}_{i+} \hat{I}_{j-} + \hat{I}_{i-} \hat{I}_{j+}) \\ & + T_{ij}^{\text{aniso}} [\hat{I}_{iz} \hat{I}_{jz} - \frac{1}{4} (\hat{I}_{i+} \hat{I}_{j-} + \hat{I}_{i-} \hat{I}_{j+})] \} \end{aligned} \quad (22)$$

T'^{aniso} of equation (18) can be expanded in terms of a molecule-fixed system (x, y, z) as

$$\begin{aligned} T'^{\text{aniso}} = & \frac{2}{3} S_{zz} [T_{zz} - \frac{1}{2} (T_{xx} + T_{yy})] + \frac{1}{3} (S_{xx} - S_{yy}) (T_{xx} - T_{yy}) \\ & + \frac{2}{3} S_{xy} (T_{xy} + T_{yx}) + \frac{2}{3} S_{xz} (T_{xz} + T_{zx}) \\ & + \frac{2}{3} S_{yz} (T_{yz} + T_{zy}) \end{aligned} \quad (23)$$

In the Hamiltonian, $T_{ij}^{\text{iso}} = J_{ij}^{\text{iso}} = J_{ij}$ is the indirect spin-spin coupling constant and $T_{ij}^{\text{aniso}} = J_{ij}^{\text{aniso}} + 2D_{ij}$, where J_{ij}^{aniso} is the pseudodipolar coupling, which cannot easily be separated from the direct coupling (see Section 9.1.2).

$D_{ij} = -(\mu_0 \hbar \gamma_i \gamma_j / 8\pi^2 r_{ij}^3) S_{ij}$ contains the structural information.

In an experiment, the measured T_{ij}^{aniso} is usually called $2D_{ij}$, so that the parameter D_{ij} contains a contribution of $\frac{1}{2} J_{ij}^{\text{aniso}}$.

In conclusion, it may be stated that the Hamiltonian of an oriented spin system can be derived from that of the isotropic system simply by adding the anisotropic shift component to the shift part, and substituting $J_{ij} + 2D_{ij}$ for J_{ij} in the diagonal contributions to the Hamiltonian and $J_{ij} - D_{ij}$ for J_{ij} in the off-diagonal contributions.

5.3 Nomenclature and Characterization of Spectra

Although the spectra of oriented molecules can be calculated by a relatively minor modification of the Hamiltonian of the nonoriented spin system, there are no simple transformations with, for example, effective Larmor frequencies or effective coupling constants (as in subspectra) that transform the spectrum of an oriented system into that of a nonoriented system; consequently, there are some clear differences. First of all, the notion of magnetic equivalence must be redefined, and the term ‘full equivalence’, which means the same coupling between nuclei of same chemical shift, must be introduced,

because, in oriented systems, the spectra of magnetically equivalent nuclei such as the protons of benzene (which, when nonoriented, displays one transition) depend upon all the direct as well as the indirect coupling constants. Only in a fully equivalent group such as CH_3 is the spectrum of the oriented molecule independent of $J(\text{H,H})$. However, it still displays information on the D s: spectra of n fully equivalent nuclei of spin- $\frac{1}{2}$ consist of n -line multiplets with spacing $3D$. Magnetic equivalence does not exist for $I \geq 1$.

Also, the term 'weak coupling', which in normal NMR is usually (but wrongly!) defined as $J_{\text{AX}} \ll \delta_{\text{AX}}$ and which should actually be defined as $J^2/\delta_{\text{AX}} \ll$ (measurable difference in line position), loses its meaning in oriented NMR. The exception is when, in a system of, for example, three spins ABC, there is one direct coupling D_{AB} that exceeds all the δ s, J s, and other D s. In this case, in analogy with an ABX spectrum, the C nucleus is isolated and acts as a weakly coupled X nucleus; i.e., we observe AB doublets with splitting of $3D_{\text{AB}}$ with effective Larmor frequencies, i.e., centers of gravity, at

$$\frac{1}{2}(\nu_{\text{A}} + \nu_{\text{B}}) \pm \frac{1}{2}[\frac{1}{2}(J_{\text{AC}} + J_{\text{BC}}) + (D_{\text{AC}} + D_{\text{BC}})] \quad (24)$$

The appearance of a spectrum of two oriented nuclei AB is similar to that of the nonoriented system only if either J or δ and J are large with respect to D . In all other cases, i.e., $J = \delta = D$, $\delta = D > J$, $J = D < \delta$, $\delta = J < D$, and $J = D > \delta$, the intensity pattern is reversed, i.e., the inner lines are weaker.

Finally, a peculiarity of the spectra of oriented systems of three nuclei $\text{AA}'\text{A}''$ in which the D s dominate may be mentioned. These spectra have a continuum of solutions, because only $D_{\text{AA}'} + D_{\text{AA}''} + D_{\text{A}'\text{A}''}$ as well as $D_{\text{AA}'} D_{\text{AA}''} + D_{\text{AA}'} D_{\text{A}'\text{A}''} + D_{\text{AA}''} D_{\text{A}'\text{A}''}$ can be determined, even if the line intensity is also considered.

5.4 Spectral Analysis

Spectra of oriented molecules are usually analyzed with the help of computers. Various programs such as LEQUOR,¹⁶ which has been derived from LAOCOON simply by modification of the Hamiltonian (see Section 5.3), are available. The analysis is often quite complex, because, even if an appropriate molecular geometry can be guessed, the degrees of order cannot be predicted. In the fitting process illustrated in Figure 2, the indirect couplings J as fixed parameters as well as starting values of isotropic chemical shifts are taken from spectra of the nonoriented molecules, and D s as well as δ s are then iterated. As an example of a spectral analysis, we cite the proton spectrum of benzene shown in Figure 3. It is, of course, not representative of a typical structure determination, because the protons must form a hexagon. However, it will be interesting for a discussion of effects that must be corrected, such as vibration and deformation (see Section 9). The analysis of the spectrum is relatively trivial, because the degree of order is the only principal unknown, and the assignment of transitions is possible by inspection of a series of calculated spectra with assumed perfect hexagonal structure and with variable S value. Such inspection methods still work for two different degrees of order and with a two-dimensional display of the calculated spectra. For more than two unknown S values, however, the method fails.

Coming back to the benzene case, we should mention that the measured direct coupling constants do not quite agree

with the hexagonal values, and depend quite strongly upon the liquid crystal solvent. The observed ranges in smectic, nematic lyotropic, mixed cholesteric, and nematic thermotropic solvents are for r_p/r_o (which should be 2.000) from 1.989 to 2.004 and for r_m/r_o (which should be 1.732) from 1.725 to 1.735.

In order to simplify the analysis procedure, two different approaches have been developed. In the first, an approximate guessed molecular structure is kept fixed during the iterative analysis of the spectrum, and only the S values are varied. The great advantage of such a scheme is the reduction of the number of unknowns for n nuclei of the order of n^2 to less than five, depending upon the symmetry, i.e., a very low number of assigned transitions allows a more rapid approach to an approximate solution. Of course, a normal analysis with a maximum of assigned transitions has to be performed at the end of this procedure, because the assumed geometry is not quite correct. However, the assignment of lines is then quite easy.

In the second simplifying approach, programs were developed that analyze the spectra automatically, i.e., no line assignment is necessary. The programs were based on the observation that in a fit that minimizes the average square deviation of line positions, there are local minima of this function that stop the fitting process whenever a transition of the measured spectrum coincides accidentally with one of the calculated spectrum. Therefore, in order to fit a spectrum, its properties should be 'smeared out', and only the rough features should be considered—as is actually done in analysis 'by hand'. For this purpose, either the lines may be artificially broadened to begin with and subsequently sharpened again during the fitting process, or the whole spectral information may be transformed into values, each of which characterizes a property of the spectrum but is independent of the others (integral transformations). Then the fit consists of a comparison of experimental with theoretical transforms. Again, a 'smeared out' appearance of the information is obtained—this time by using first a limited number of transforms (e.g., the lowest frequency Fourier transforms) and subsequently increasing the number during the fit as, for example, in the program STREAK.¹⁷ Automatic analysis programs have successfully been used in practice.

5.5 Simplification of Spectra

5.5.1 Decoupling

The number of intense transitions for spectra of n spins $\frac{1}{2}$ increases as $n2^{n-1}$; i.e., a system of eight spins with approximately 1000 transitions is already quite tedious to analyze. For larger systems, one way out of trouble is a partial deuteration of the molecule, which, owing to the spin 1 of the deuterons, at first makes the proton spectrum more complex, although all the couplings to deuterons are reduced by a factor of 6.514 with respect to the proton case. The spectrum can then be simplified considerably by decoupling the deuterons¹⁸ from the protons by irradiation at the center of gravity of the deuteron quadrupolar-split doublets, inducing double quantum transitions between the two deuteron levels with spins +1 and -1.

5.5.2 Two-Dimensional Spectroscopy

An alternative approach¹⁹ is provided by random deuteration and subsequent use of quantum filtered and

Figure 2 Schematic representation of spectral analysis: (a) automatic, comparison of experimental with theoretical data via integral transformations of spectrum (see Section 5.4); (b) normal ‘hand’ analysis with line assignment and iteration of σ_i , J_{ij} , and D_{ij} ; (c) ‘hand’ analysis, with line assignment and assumed approximate molecular geometry, iteration of σ_i , J_{ij} , and S_{ij}

Figure 3 Proton spectrum of benzene, 6 mol% partially oriented in the nematic liquid crystal solvent ZLI 1132 (see Table 4) at 303 K

two-dimensional correlated spectroscopy, which leads to the separation of spectra of isotopically different molecules, each, of course, with a reduced number of protons.

5.5.3 Sample Rotation

Samples can be rotated²⁰ near the magic angle orientation with spinning speeds of a few kilohertz, and the direct couplings are thus reduced so that two-dimensional techniques, which normally fail in the strongly coupled spin systems of oriented molecules, become possible and assist the analysis.

5.5.4 Satellite Enhancement

X-nucleus satellite spectra of protons are very useful for a determination of structure information on, for example, ^{13}C and ^{15}N . Although they are usually quite weak because of the low abundance of the X nucleus, they are still easier to detect

Table 2 Gain Factor in the Signal-to-Noise Ratio if Direct Coupling D_{HX} is Not Observed in the X Spectrum but as a Satellite in the H Spectrum

Nucleus	Gain factor	Nucleus	Gain factor
H	1	^{77}Se	144
^{13}C	63	^{107}Ag	15 106
^{15}N	961	^{113}Cd	91
^{29}Si	128	^{117}Sn	22
^{31}P	15	^{199}Hg	176
^{57}Fe	29 590	^{195}Pt	101

than the X spectra. As an example, the gain in signal-to-noise ratio which is obtained if the C–H direct coupling is observed as a satellite in the proton spectrum and not as a splitting in the ^{13}C spectrum is 63. The corresponding gain for ^{15}N is 961. Further values are shown in Table 2.

In order to separate the weak satellite spectra from the much stronger pure proton spectrum, special difference methods may be applied. Thus, for instance, the ^1H spectrum minus a $^1\text{H}\{^{13}\text{C}\}$ spectrum gives simply the satellite spectrum with positive amplitude as well as the ^1H spectrum with total intensity equal to the ^{13}C satellite spectrum with negative amplitude.

5.5.5 Multiple Quantum Transitions

In normal NMR, we always observe one quantum transitions, i.e., the energy or frequency of the transitions is obtained as the difference of two eigenvalues of two Hamiltonian submatrices corresponding to total spins m and $m - 1$. For systems of more than two spins without symmetry, these matrices may have dimensions of 3×3 or larger, so that usually the transitions are not given by analytical expressions in the NMR parameters. In systems with symmetry, the breakdown of the Hamiltonian matrix into submatrices corresponding to symmetry species is responsible for transitions that can be expressed analytically.

A method that provides simplification of the information is the induction of multiple quantum transitions.²¹ Thus, for instance, in a system of n spins $\frac{1}{2}$, the transition from total spin $+\frac{1}{2}n$ to $-\frac{1}{2}n$, i.e., the n quantum transition, is observed as the average Larmor frequency of the n nuclei, because in both eigenvalues all the couplings contribute equally and therefore disappear in the difference.

In the benzene six-spin system, for example, the six quantum transition is located at ν_{H} (benzene), but the five quantum transitions are also still simple sums of J and D couplings, because in the Hamiltonian subsystems corresponding to the symmetry species A_1 , these transitions connect 1×1 submatrices. Some of the four quantum transitions (species A_1 , B_1 , E_1 , E_2) again appear at ν_{H} (benzene), but some others (species A_1) are nonanalytical. The main simplification, however, lies in the drastic reduction in the number of transitions and in the easy identification of their origin, which, with the help of a computer, allows faster analysis. On the other hand, the method has not found routine application, because the measuring time for a reasonable signal-to-noise ratio is large.

5.5.6 Very High Fields

Except for an increased signal-to-noise ratio, very high fields do not contribute to the simplification of spectra of oriented molecules, because, even for 750 MHz proton spectra, the weak coupling condition limits D values to less than 100 Hz if deviations from the weak coupling behavior are not to exceed 1 Hz.

On the other hand, high magnetic fields are able to orient molecules whose anisotropy of diamagnetic susceptibility is large enough, so that dipolar splittings may be observed in 'isotropic' liquids. This effect is, however, small, because the degrees of orientation that may be reached are 10^{-6} – 10^{-5} for diamagnetic and 10^{-5} – 10^{-4} for paramagnetic molecules, whereas in liquid crystals we easily reach 10^{-2} – 10^{-1} . Orientation by magnetic field for determining accurate structures is therefore out of the question.

6 DETERMINATION OF STRUCTURE FROM DIPOLAR COUPLING

For the determination of molecular structure from measured direct couplings, computer programs such as SHAPE²² may be used, which, starting from a guessed molecular geometry, defined symmetries, and an assumed basis, calculates a set of theoretical direct couplings that is iteratively compared with the measured values weighted according to their variance until a minimum square deviation is found. As a result of the fit, the relative internuclear distances, absolute angles, and S values, as well as errors (variances and covariances), are obtained. For the calculation of error propagation, the mean-square error of the spectral fit is fed into the program. If this error is smaller than the average line position error (i.e., the problem is just determined or slightly overdetermined) then the latter is used as input. Actually, it is generally meaningful to use an increased error (e.g., 1–2 Hz) that takes into account the imprecision of the theoretical assumptions made in the corrections (see Section 9.2).

7 POSSIBLE ACCURACY OF STRUCTURE DETERMINATION

Most observed direct couplings are in the range of 10^2 – 10^3 Hz. It is usually possible to obtain linewidths of the order of 1 Hz, so that 10^{-1} Hz can definitely be determined (sometimes even 10^{-2} Hz), so that the relative accuracy of couplings is usually 10^{-4} . Since the internuclear distances are proportional to $D^{-1/3}$, the relative accuracy of the distances is also further increased to 3×10^{-5} . Consequently, distances should, in principle, be measurable with an accuracy of at least 10^{-2} pm. Unfortunately, this accuracy is not meaningful, because several approximations are made in the necessary corrections to the measured direct couplings. These are neglect of pseudodipolar coupling contributions to the measured D s, limited accuracy in the vibration corrections, and assumptions made in the deformation corrections (see Section 9.2.2).

Taking these facts into account, it is possible to state that an accuracy of distance determination by NMR of oriented molecules exceeding 0.1 pm in bond lengths and 0.1° in bond angles is definitely unrealistic. However 1 pm may be measured reliably.

8 MOLECULES STUDIED

Between 1968 and 1983, the structures of over 500 molecules were determined by NMR in liquid crystal solvents. The initial intensity of research, with approximately 30 structures per year, has more recently been reduced to approximately 10 structures per year. On the other hand, the interest in high-resolution NMR in liquid crystals in general has steadily increased from 40–50 papers per year in the 1970s to 80–100 papers per year in the 1980s and early 1990s.

The reasons for the reduction in structure studies are obviously that practically all the interesting small molecules with six or less spins have already been considered, and the expansion to larger spin systems is still slow. For the first studied 500 molecules, the relative contributions of systems with 4, 5, 6, 7, and 8 or more spins were 30, 20, 30, 10, and 10%. These ratios have not changed appreciably since then. Still ^1H with and without satellites and ^{13}C are the most studied nuclei, with additional interest in ^2H , ^{19}F , and ^{31}P , and occasional interest in ^{11}B , ^{14}N , ^{15}N , ^{17}O , ^{111}Cd , ^{113}Cd , ^{119}Sn , and ^{199}Hg . The spectra of relatively few molecules (less than 20) have so far been ‘properly’ analyzed in the sense that vibrational as well as deformational corrections have been performed. Structural data obtained by NMR of oriented molecules have been collected in books and reviews.^{23,24}

9 FACTORS LIMITING THE ACCURACY OF STRUCTURE DETERMINATION

9.1 Principal Limits or Factors That at Present Practically Cannot Be Corrected

9.1.1 Signal-to-Noise Ratio

One of the limiting factors to the accuracy of structure determination is the signal-to-noise ratio (S/N) of the spectra, because the errors in line position (Δ) depend upon the point resolution ν_p , the linewidth ν_L and S/N as follows:

$$\Delta = \left(\frac{\nu_L^2}{\text{S/N}} + \frac{\nu_p^2}{12} \right)^{1/2} \quad (25)$$

The S/N can be increased by a factor of n if the measurement time is increased by n^2 .

In ^{13}C satellites of proton spectra, Δ is usually 10 times larger than in the strong proton transitions. Consequently, the accuracy of the D_{HH} s exceeds that of the D_{CH} s.

9.1.2 Anisotropy of Indirect Coupling Constants (Pseudodipolar Coupling)

As pointed out in Section 7, the measured direct coupling constants contain contributions from the pseudodipolar coupling, i.e., the anisotropy of the indirect coupling; for example, for a planar molecule with C_2 symmetry,

$$\begin{aligned} D_{ji}^{\text{exp}} &= D_{ji} + \frac{1}{2} J_{ij}^{\text{aniso}} \\ &= \frac{1}{2} (3 \cos^2 \alpha - 1) \left\{ S_{33} \left[-\frac{K}{r_{ij}^3} \frac{1}{2} (\cos^2 \Theta_3 - 1) + \frac{1}{3} \Delta J \right] \right. \\ &\quad \left. + (S_{11} - S_{22}) \right. \\ &\quad \left. \times \left[-\frac{K}{r_{ij}^3} \frac{1}{2} (\cos^2 \Theta_1 - \cos^2 \Theta_2) + \frac{1}{6} (J_{11} - J_{22}) \right] \right\} \quad (26) \end{aligned}$$

with

$$\Delta J = J_{33} - \frac{1}{2} (J_{11} + J_{22}), \quad K = \mu_0 \hbar \gamma_i \gamma_j / 8\pi^2 \quad (27)$$

If $J_{ij}^{\text{iso}} = \frac{1}{3} (J_{11} + J_{22} + J_{33})$ is small then usually the individual components $J_{\mu\mu}$ will also be small, i.e., the contribution of J^{aniso} may be neglected. This is certainly the case for couplings between two protons, for which $J_{ij}^{\text{aniso}}/D_{ij}$ has been found to be of the order of 10^{-4} . Also, for one-bond C–H couplings, $J_{ij}^{\text{aniso}}/D_{ij}$ has been determined experimentally as well as theoretically to be smaller than 10^{-3} . For other nuclear pairs, such as C–F, F–F, C–C, and C–N, the values are between 10^{-2} and 10^{-1} . Unfortunately J anisotropies are very difficult to determine—at any rate, vibrational as well as deformational corrections have to be performed in order to obtain meaningful results. Furthermore, the determinacy problem arises.²⁵

If a molecular structure is defined by G and the order by O parameters then the number of measured couplings C must exceed the sum $G + O$. If we also count the J^{aniso} contributions, of which we have CO , then the condition

$$C \setminus G + O + CO \quad (28)$$

is only fulfilled if several spectra (n) are recorded:

$$nC \setminus G + nO + CO \quad (29)$$

i.e.,

$$n(C - O) \setminus G + CO \quad (30)$$

which is possible for large n if $C > O$.

The situation is even worse if the necessary deformational corrections are also considered. They introduce, instead of the O order parameters, a number of unknowns equal to twice the number of different bond types of the studied molecule, a figure that is always larger than O .

In conclusion, the neglect of J^{aniso} limits the obtainable accuracy in structure determination. As long as only H–H and C–H dipolar couplings are considered, the relative error is of the order of 3×10^{-4} , i.e., the contribution is of similar magnitude to that of the imprecise vibrational correction (see Section 9.2.1).

9.2 Factors That Can Be Corrected

9.2.1 Molecular Vibration

Apparent geometries of rigid solute molecules calculated from NMR spectra in nematic solvents must be corrected for effects due to their vibrational motions. These motions affect the direct couplings not only via the time dependence of the internuclear distance r_{ij} but also that of the degree of order of the ij axis. (The molecular degree of order is assumed to be constant during the vibrational period.) If we consider the substantial mean amplitudes of vibration of, for example, a C–H bond (7.8 pm) or of a nonbonded pair H–C–H (13.5 pm), it is obvious that different structure determination methods will, if uncorrected, provide different results for the average of

r_{ij} : $\langle r_{ij} \rangle$ from electron diffraction, $\langle r_{ij}^{-2} \rangle^{-1/2}$ from microwave spectroscopy, and $\langle r_{ij}^{-3} \rangle^{-1/3}$ from NMR.

An expansion for small amplitudes of vibration provides the relation

$$D_{ij}^{\text{exp}} = D_{ij}^e + D_{ij}^a + D_{ij}^h \quad (31)$$

where D_{ij}^e corresponds to the hypothetical molecular equilibrium structure that minimizes the electronic potential within the Born–Oppenheimer approximation. D^a is the anharmonic term, which for a pair of nuclei at distance R on the z axis is given by $D^a = -3\langle \Delta z \rangle D^e/R$, where $\langle \Delta z \rangle$ is the average z -vibration amplitude. D^h is the harmonic term, which is given by $D^h = 6(C^{\parallel} - C^{\perp})D^e/R^2$, where $C^{\parallel}$ and $C^{\perp}$ are the diagonal terms of the covariance matrix of vibrations.

For the vibrational corrections of NMR data, the force field of the molecule under study must be known. Computer programs are available (e.g., VIBR²⁶) that from a force field and the corresponding assumed molecular geometry derive normal coordinates, vibrational frequencies (as a test), covariance matrices of quadratic displacements, and, finally, D_{ij}^h . The corrected coupling $D_{ij} - D_{ij}^h = D_{ij}^e + D_{ij}^a$ corresponds to a so-called additive r_α structure, i.e., to the average projection of the bond length onto a line joining the equilibrium positions.

Owing to their R^{-2} dependence, the harmonic vibrational corrections are particularly large for directly bonded nuclei such as C–H, for which the correction, for example, in benzene, is of the order of 8%, leading to an error in the bond length of close to 3% if it is not taken into account (see Table 3).

Relative corrections can also become particularly large for planar molecules of which two perpendicular axes in the plane have oppositely signed degrees of order. From Table 3, it can be concluded that if the required relative structural precision is of the order of 0.5% then, for not too small degrees of order and pure proton structure, harmonic corrections are not required.

The accuracy of harmonic vibrational corrections depends upon the force field, and is also affected by the approximation of r_e by r_α in the derivation of the corrections. However, the errors introduced are generally smaller than 4% (C–H bond) of the correction, corresponding to distance errors of 0.1 pm.

Anharmonic corrections may be computed by the program AVIBR²⁷ if the cubic force constants are available. Even if they are not, approximate corrections can still be calculated. A considerable part of the anharmonicity is artificial in that it originates from the use of rectilinear coordinates for a curvilinear pure harmonic motion. Obviously, this part can

be derived from the harmonic force constants. The intrinsic anharmonicity stems principally from the potential functions associated with bond stretching. Using the Morse potential $V(\Delta r) = D[1 - \exp(-a \Delta r)]^2$ and expanding in terms of the bond stretch coordinate, it is possible to derive the cubic force constant in terms of the quadratic one as $f_{\text{cubic}} = -3af_{\text{quad}}$, where a turns out to be 0.02 pm^{-1} , even for very different bonds.

9.2.2 Molecular Deformation

The energy of molecules dissolved in liquid crystals contains contributions from their orientation and also from their vibration (quadratic in the normal coordinates). Because the vibrating molecule is subject to external forces, there must be a further contribution that is linear in the normal coordinates Q_k ($U_k Q_k$, where $U_k = \partial U_{\text{ext}} / \partial Q_k|_e$). This linear term, if added to the quadratic one ($\omega_k^2 Q_k^2$), shifts the energy minimum, i.e., the nuclei vibrate around a position displaced by U_k / ω_k^2 . In other words, the molecules are deformed, the deformation depending upon the orientation of the molecule with respect to the liquid crystal director. Various names have been used for this phenomenon—for example, vibrational–rotational interaction or correlated deformation. The fact that to a certain orientation of a molecule there corresponds a deformation can also be reinterpreted as follows: orientation of a molecule requires that certain torques be applied to the bonds, and these torques will of course deform the molecular structure.

Correlated deformation²⁸ leads to additional terms in direct couplings D^d :

$$D^d = -K \sum_k \frac{1}{\omega_k^2} \left[\frac{3}{10} \sum_{\alpha\beta} \frac{\partial \Phi_{\alpha\beta}^{ij}}{\partial Q_k} \frac{\partial A_{\alpha\beta}}{\partial Q_k} + \frac{2}{7} \sum_{\alpha\beta\mu} \left(3 \frac{\partial \Phi_{\alpha\mu}^{ij}}{\partial Q_k} \frac{\partial A_{\beta\mu}}{\partial Q_k} - \frac{\partial \Phi_{\mu\mu}^{ij}}{\partial Q_k} \frac{\partial A_{\alpha\beta}}{\partial Q_k} \right) S_{\alpha\beta} \right] \quad (32)$$

where

$$\Phi_{\alpha\beta}^{ij} = \langle \cos \Theta_{ij\alpha} \cos \Theta_{ij\beta} / r_{ij}^3 \rangle \quad (33)$$

$\Theta_{ij\alpha}$ is the angle between internuclear vector r_{ij} and the α axis of the reference system, and $A_{\alpha\beta}$ are the elements of the interaction tensor, where

$$U_{\text{ext}} = -\frac{1}{2} \sum_{\alpha\beta} A_{\alpha\beta} (3 \cos \Theta_\alpha \cos \Theta_\beta - \delta_{\alpha\beta}) \quad (34)$$

with Θ_α the angle between the α axis of the reference system and the liquid crystal director. As pointed out above, the interaction tensor must also define the order tensor of the molecule:

$$S_{\alpha\beta} = \frac{1}{Z_c} \int (3 \cos \Theta_\alpha \cos \Theta_\beta - \delta_{\alpha\beta}) \exp\left(-\frac{U_{\text{ext}}}{k_B T}\right) d\Omega \quad (35)$$

$$Z_c = \int \exp\left(-\frac{U_{\text{ext}}}{k_B T}\right) d\Omega \quad (36)$$

where Ω is the orientation of the molecular axis with respect to the laboratory-fixed frame.

It is interesting to note that even for $S_{\alpha\beta} = 0$ there is a remaining contribution to D^d . This explains the well known

Table 3 Harmonic Vibrational corrections for Benzene, $D_{\text{corr}} = D_{\text{exp}} (1 + \alpha)$

Coupling	100 α
D_{HH}^o	+1.418
D_{HH}^m	+0.719
D_{HH}^p	+0.446
D_{CH}	+8.054
D_{CH}^o	+1.845
D_{CH}^m	+0.677
D_{CH}^p	+0.384

fact that tetrahedral molecules dissolved in liquid crystals also display direct couplings. Obviously, this contribution increases drastically the relative importance of deformational corrections for molecules with small degrees of order. Furthermore, it should be mentioned that actual distortions of molecules (e.g., a change in bond angle between parallel and perpendicular orientations of the molecule with respect to the liquid crystal director) are amplified considerably by the correlated deformation process, and may lead, if uncorrected, to apparent distortions of the order of 10 times the actual distortion.

In order to determine solvent-independent molecular structures, the measured couplings must definitely be corrected for deformation. Since nothing is known initially about the interaction tensor, the elements $A_{\mu\nu}$ must be treated as unknown. The simplest approach is the assumption that the tensor $\mathbf{A}$ is a sum of individual bond interactions and that bond stretching may be neglected with respect to bond bending. In the iterative determination of molecular structure, not only the nuclear positions but also bond interaction tensors, i.e., their anisotropies $\Delta A = A_{zz} - \frac{1}{2}(A_{xx} + A_{yy})$ and asymmetries $\eta = (A_{yy} - A_{xx})/A_{zz}$, are iterated. As shown above, the A s simultaneously determine the degrees of order (see also Section 3). In such a fit, the number of unknowns increases, but data obtained in various solvents may be fitted in one run.

The corresponding program MASTER²⁹ (see Figure 4) needs an input of the force field with the corresponding molecular structure and a definition of bonds; it then calculates in a modified subprogram of the type VIBR (see Section 9.2.1) the normal coordinates, the vibrational frequencies, and the basis for the harmonic contributions to the direct couplings and for the derivatives of direct coupling tensors and interaction

tensors with respect to the normal coordinates. These data are fed into a modified version of SHAPE (see Section 6), together with the definition of the iteration parameters, experimental direct couplings, symmetries, gyrometric ratios, guessed starting structure, and guessed starting interaction tensors. SHAPE then calculates order parameters (S) from interaction parameters (ΔA , η_A) by numerical integration, the equilibrium D s (D^e); harmonic corrections (D^h) and deformation corrections (D^d). By subsequent iteration of ΔA , η_A , and molecular structure, a minimum RMS error is obtained, and the output of the program lists molecular structure, interaction parameters, and δ values, with corresponding errors.

As an example of deformational corrections we compare in Table 4 the relative deviations of distance ratio in benzene $\Delta(r_\mu/r_\nu)$ derived from the measured direct couplings, with the data corrected for vibration only and for vibration as well as deformation from the theoretical hexagonal values.

The table shows that the effects of vibrational and deformational corrections on the resulting structure can be of similar magnitude; however, their signs may be opposite, so that the uncorrected structure can be closer to the real structure than the one corrected for harmonic vibration. A typical example is the solvent EBBA, in which the deviation from a hexagon is increased by the harmonic vibrational correction, but is reduced to zero by the deformational correction. Table 4 also demonstrates that, because the sign of the deformational correction can be positive or negative, depending upon the liquid crystal, it is possible to minimize the deformation—in particular, the C–H bending contribution—by using a mixture of solvents. There is, however, no ideal solvent in general, because different bond interactions may contribute to the distortion even if the C–H contribution disappears. The program MASTER, and the underlying theory, have been very successful. They explain the direct couplings in tetrahedral molecules, the deviation from the apparent benzene structure from the hexagonal one after harmonic vibrational corrections, the methyl angle variation with solvent in molecules of the type CH_3X with an apparent distortion of 2° and an actual one of 0.2° , and the apparent variation of the distance ratio $r_{\text{CH}}/r_{\text{CN}}$ by 50% in HCN for small S values, as well as disagreements between NMR and different methods of structure determination (e.g., in the deformation of benzene by substituents).

10 COMBINATION OF NMR STRUCTURAL INFORMATION WITH DATA FROM OTHER SPECTROSCOPIES

Because of their large coupling constants, the positions of protons can be determined with high accuracy. Positions of carbon or nitrogen are obtainable with less accuracy. Nuclei such as oxygen, sulfur, or chlorine with spin $I \geq 1$ cannot be located, because, owing to their quadrupolar relaxation, they are effectively decoupled from the other nuclei. Deuterium and quadrupolar nuclei in highly symmetrical structural environments are exceptions. Their dipolar (as well as quadrupolar) interactions can be measured.

The lack of information has induced several authors right from the beginning of work on NMR of oriented molecules

Figure 4 Schematic representation of molecular structure determination with corrections for harmonic vibrations and for deformation (program MASTER)

Table 4 Relative Deviations $\Delta(r_\mu/r_\nu) = [(r_\mu/r_\nu) - (r_\mu/r_\nu)_{\text{hex}}]/(r_\mu/r_\nu)_{\text{hex}}$ from Theoretical Hexagonal Distance Ratios for Protons $r_p/r_o = 2.0000$ and $r_p/r_m = 2/\sqrt{3} = 1.1547$ in Benzene (accuracy $> \pm 0.7$); A Deviation of 10^{-4} Corresponds to 0.025 pm in r_o , or 0.043 pm in r_m , or 0.05 pm in r_p

^a1132 = mixture of three *trans*-4-*n*-alkyl(4-cyanophenyl)cyclohexanes and *trans*-4-*n*-pentyl(4'-cyanobiphenyl-4-yl)cyclohexane; EBBA = *n*-(*p*-ethoxybenzylidene)-*p*-*n*-butylaniline.

to combine information from different spectroscopies with NMR.^{30,31} Other spectroscopies, each of which has its own limitations, can profit from this. For example, electron diffraction and microwave spectroscopy provide absolute internuclear distances with reliable heavy atom positions, whereas NMR gives relative distances with high accuracy for the location of the light nucleus, namely the proton. In combined fits, relative weights proportional to the inverse square of their uncertainties are given to the parameters. Of course, harmonic vibrational corrections must be performed for all the spectroscopies, and, in particular, deformational corrections are essential for NMR in order to remove solvent effects. Furthermore, in NMR, couplings to heavy nuclei should be excluded, because of their pseudodipolar coupling component. Finally, variances as well as covariances should be considered.

11 CONCLUSIONS

NMR of oriented molecules is a simple and fast method for obtaining information on molecular structure in the form of highly accurate direct coupling constants. It can be used for groups of up to 10 magnetic nuclei (with spin- $\frac{1}{2}$) in small molecules or in larger molecules in which the remaining nuclei are decoupled. The method provides accurate proton positions, which are difficult to obtain by other spectroscopies. It can definitely compete with microwave spectroscopy and electron diffraction and, for small molecules, with X-ray diffraction.

The main disadvantage of the method lies in the fact that it studies molecules that are not free but are dissolved in liquid crystals, which deform the molecular structure by anisotropic interaction and make it solvent-dependent. However, the solvent dependence can now be removed by calculation of deformational corrections. In these calculations, approximations have to be made in order to reduce the number of unknowns:

1. deformations are taken to consist of bond bending exclusively, and stretching is neglected;
2. the interaction is assumed to be described as a sum of bond contributions.

These simplifications, together with the neglect of pseudodipolar coupling, lead to a reduction of structural accuracy, which, on the basis of measurement errors, could easily have reached 0.01 pm, to approximately 0.1 pm in bond lengths and 0.1° in angles.

1 INTRODUCTION

The direct dipole–dipole interaction between nuclear spins plays a dominant role in magnetic resonance. Several kilohertz in magnitude, it causes severe line broadening of NMR lines in solids owing to the presence of a large number of coupled spins. Anisotropic reorientation coupled with translational diffusion of molecules embedded in ordered matrices, such as a liquid crystalline medium, yields extremely interesting NMR spectra.¹ In such cases, the intermolecular dipolar interactions are averaged to zero, and the intramolecular interactions, scaled by the order parameter, are reduced to a few hundreds of hertz. As a result, only a finite number of spins are dipolar-coupled, yielding a large number of sharp and often well-resolved spectral lines. These dipolar-coupled spectra are extremely useful, and contain detailed information on the conformation, symmetry and anisotropy of reorientation of the molecules. However, since the dipolar couplings are often large compared with the chemical shifts, the spectra exhibit strong coupling features, making the analysis of such spectra nontrivial.^{2–5} Only in some simple spin systems is the Hamiltonian analytically diagonalizable, allowing straightforward interpretation of the spectra. In most cases, one has to perform a numerical analysis using iterative computer programs such as LAOCOON⁶ and its various modifications.^{4,7,8} The input to these programs comprises the line frequencies, intensities, and initial parameters of the Hamiltonian. Trapping of the algorithm into local minima is a frequently encountered problem, and any additional information about the spectrum, the spin system, and the molecular reorientations is extremely useful.

Two-dimensional (2D) NMR spectroscopy has played a significant role in simplifying spectra and in often providing the key information. The various 2D NMR studies of oriented molecules discussed in this article are classified into the following categories:

1. resolved spectroscopy;
2. experiments utilizing transverse spin orders using single and multiple quantum coherences;

3. experiments utilizing longitudinal spin orders such as NOESY and Z-COSY.

The emphasis in this article is on proton spectra of small molecules oriented in liquid crystal matrices. Reference may be made to a review on this subject,⁹ and periodic reviews of NMR of oriented molecules.¹⁰

2 TWO-DIMENSIONAL SPIN ECHO RESOLVED SPECTROSCOPY

The spin echo 2D resolved experiment utilizes a pulse sequence ($90^\circ, \frac{1}{2}t_1, 180^\circ, \frac{1}{2}t_1, t_2$). The 180° pulse reverses the sign of all terms linear in spin operators over which the 180° pulse acts, and leaves all bilinear terms invariant. For homonuclear (spin- $\frac{1}{2}$) spins, the various terms contributing to the spectra of oriented molecules are

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_J + \hat{\mathcal{H}}_D \quad (1)$$

where $\hat{\mathcal{H}}_Z$ involves chemical shift terms linear in spin operators, and $\hat{\mathcal{H}}_J$ and $\hat{\mathcal{H}}_D$ are the indirect spin–spin and direct dipole–dipole couplings, respectively, which are both bilinear in spin operators. The 180° pulse reverses the sign of $\hat{\mathcal{H}}_Z$ and leaves $\hat{\mathcal{H}}_J$ and $\hat{\mathcal{H}}_D$ invariant. If all the terms commute, as happens only in weakly coupled isotropic cases where $\hat{\mathcal{H}}_D$ is absent and $\hat{\mathcal{H}}_Z \gg \hat{\mathcal{H}}_J$, then $\hat{\mathcal{H}}_Z$ refocuses, and the effective Hamiltonian is simply $\hat{\mathcal{H}}_J$. In such cases, the 2D spin echo spectrum consists of a simple separation of chemical shifts and couplings, with the multiplets of each chemical site appearing along a 45° line from the $\omega_1 = 0$ axis^{11,12} (see *Two-Dimensional J-Resolved Spectroscopy*). When the various terms in equation (1) do not commute, the 180° pulse causes coherence transfer between various transitions, and calculations performed for strongly coupled spins show that the line intensities and frequencies along the ω_1 direction are modified and that there are additional lines in the 2D spectra.^{13,14}

The first application of this experiment in oriented systems was on an AB spin system formed by the protons of 1-thio-3-selenole-2-thione oriented in MBBA.¹⁵ The 1D spectrum of the two spins consists of four lines symmetrically displaced from the average chemical shift. The difference between the outer and inner lines is the sum $|J_{AB} + 2D_{AB}|$. To assign the lines, one needs additional information, which can be provided by conventional double resonance experiments or by the above 2D resolved experiment. The 2D resolved experiment has eight lines, two of which appear with negative intensity (Figure 1). There are four lines of equal intensity along the ω_1 dimension, uniquely identifying the parameter $|J_{AB} + 2D_{AB}|$.¹⁵

Another 2D spin echo study has been carried out on the AB₂ spin system of 1-bromo-2,6-dinitrobenzene oriented in the room temperature nematic, Merck Phase V.¹⁶ Significant rf inhomogeneity gave rise to artifacts in the spectra, which were simulated as errors in the refocusing 180° pulse. Errors in the 180° pulse cause additional coherence transfer pathways of the type obtained in spin echo correlated spectroscopy (SECSY),¹⁷ and such spectra thus have features of resolved spectroscopy and SECSY, both affected by strong couplings.

Accurate values for homonuclear dipolar couplings have been extracted from 1D spin echo spectroscopy of oriented

Figure 1 Phase-sensitive spin echo 2D resolved spectrum of two strongly coupled protons of 1-thio-3-selenole-2-thione oriented in MBBA [obtained using the pulse sequence $(90^\circ, \frac{1}{2}t_1, 180^\circ, \frac{1}{2}t_1, t_2)$], recorded at 270 MHz. While the 1D spectrum consists of four lines, the 2D spectrum has eight, two of which appear with negative intensity. (Reproduced by permission of Academic Press from Khetrapal et al.¹⁵)

molecules containing AA'BB'-type spin systems, formed by the protons in *para*-substituted pyridines, which are coupled to an increasingly complex group of heteronuclei and to fluorines in tetrafluorinated benzenes.¹⁸ All the echo spectra were analyzed with a modified LAOCOON-type computer program.^{16,19} The echo spectra differed from the normal spectra principally in the presence of extra lines, which were interpreted as being due to B_1 inhomogeneity and analyzed iteratively assuming a refocusing pulse of angle $160^\circ \pm 10^\circ$.¹⁸

3 TWO-DIMENSIONAL CORRELATION SPECTROSCOPY

3.1 Single Quantum Correlation (COSY)

Two-dimensional COSY utilizes a pulse sequence $(90^\circ, t_1, 90^\circ, t_2)$, and gives cross peaks between transitions that are coupled to each other in a coupled network. The first application of COSY for the spectra of oriented molecules was to the AA'BB' spin system formed by the protons of benzoselenodiazole oriented in the liquid crystal EBBA.²⁰ The COSY spectrum separated the symmetric and antisymmetric transitions by the absence of cross peaks between them. This separation further facilitated complete identification and analysis of the antisymmetric part of the spectrum, virtually by inspection. A more detailed analysis of the intensities of the cross peaks, by changing the flip angle of the coherence transfer pulse (the second pulse of COSY), further facilitated identification of connected transitions and the assignment of resonances.²⁰

The absence of cross peaks between symmetric and antisymmetric domains in COSY has been exploited further for systems with higher symmetry. The proton spectra of oriented acetone and oriented benzene have been studied.²¹ Acetone has two rotating methyl groups, each having C_{3v} symmetry, yielding a spin system of the type A_3A_3' . The eigenstates of the Hamiltonian can be grouped into four irreducible representations, namely, A_g , A_u , G_1 , and G_{2g} , with analytical expressions available for the energies. The 2D technique separated the spectrum into four parts, with cross peaks within each group and no cross peaks between the groups. This yielded a complete symmetry filtering of all the transitions, with straightforward identification of each group and the values of the dipolar couplings. Benzene has D_{6h} symmetry, and the spin states are divided into six

irreducible representations (A_1 , A_2 , B_1 , B_2 , E_1 , and E_2). The A_2 representation has only one spin state and no transition. The remaining five representations are filtered by COSY (Figure 2) in a straightforward manner, and separate iteration of each of the domains using a modified LACONOR program yielded all the parameters in an efficient manner.²¹

Flip-angle-dependent COSY (COSY-30; $90^\circ, t_1, 30^\circ, t_2$) experiments have also been performed on the protons of *p*-dimethoxy[2H_6]benzene oriented in the liquid crystal PCH 1132, yielding information on the directly connected transitions.⁸ This system of four ring protons coupled to six methyl deuteriums forms one of the largest spin systems giving a well-resolved spectrum. The 1H - 2H dipolar couplings were focused by a spin echo experiment yielding a 10-line spectrum typical of an AA'A''A''' spin system. The connectivity information allowed a complete analysis of this spectrum, and yielded the various spectral parameters.⁸ The 2D COSY spectrum of ethyl iodide oriented in a nematic phase has also been reported.²²

3.2 Multiple Quantum Correlation

In the previous section, the use of experiments that correlate single quantum coherences with each other were described. In this section, the use of the correlation of multiple quantum coherences to single quantum coherences by 2D spectroscopy (MQ spectroscopy) and simplification of COSY spectra by multiple quantum filtering is discussed.

3.2.1 MQ Spectroscopy

Two-dimensional multiple quantum spectra are obtained by the use of the pulse sequence $(90^\circ, \tau, 90^\circ, t_1, 90^\circ, t_2)$, where the $(90^\circ, \tau, 90^\circ)$ pulse sandwich excites all orders. These multiple quantum coherences cannot be detected directly, and therefore are monitored indirectly by the use of 2D NMR. These coherences, allowed to evolve during the period t_1 , are frequency-labeled, and at the end of t_1 , a 90° pulse is used to transform them into single quantum (SQ) coherences, which are detected during the period t_2 . Thus, the 2D spectrum contains MQ frequencies in the ω_1 dimension correlated with various SQ frequencies in the ω_2 dimension.^{12,23,24} There is no net transfer of magnetization from one order to another, but only a differential transfer; therefore, many correlations appear with negative intensity. The projection of the absolute mode of the 2D spectrum on the ω_1 axis yields a 1D MQ spectrum, which can also be obtained by single point detection of the signal in t_2 .^{22,25-40} While most of the applications have been demonstrated using such one-dimensional spectra, 2D spectra have also been recorded (see *Multiple Quantum Spectroscopy of Liquid Samples*). Figure 3 shows the 2D MQ spectrum of oriented benzene.^{22,39} The spectrum becomes progressively simpler as one goes to higher multiple quantum orders, there being seven four-quantum frequencies, two five-quantum frequencies, and one six-quantum frequency present in the six-proton system of oriented benzene.

The various multiple quantum orders in Figure 3 have been separated by offsetting the carrier from the middle of the single quantum spectrum. If $\Delta\omega$ is the offset parameter then various orders are separated out by $n \Delta\omega$. The magnetic field inhomogeneity contribution to the linewidth increases

Figure 2 COSY spectrum of benzene oriented in ZLI-1167, recorded at 270 MHz. The connectivity in the B_1 symmetry domain containing lines 5, 13, 14, 14', 13', and 5' is marked in the spectrum. (Reproduced by permission of Elsevier Science Publishers BV from Rukmani and Kumar²¹)

proportionally for various MQ orders. In order to focus the field inhomogeneity, a 180° pulse has been introduced in the middle of the period t_1 , which also focuses the offset dependence of various MQ orders. The various MQ orders in such cases are separated out by the use of time proportional phase incrementation (TPPI),²⁵ in which the phases of all the pulses in the excitation sequence are incremented in sequential t_1 experiments as $\phi = \Delta\omega t_1$. This results in a separation of various MQ orders by an effective offset parameter of $n \Delta\omega$. The 180° pulse in the middle of the period t_1 leaves all homonuclear couplings invariant, and, if there are no chemical shifts, yields an undistorted MQ spectrum, for example, in benzene.^{25,26,32} However, if there are chemical shifts present along with dipolar and/or J couplings and the spectra are strongly coupled then the 180° pulse causes coherence transfer within each order, giving rise to new transitions and changed frequencies.^{13,41,42}

Using the above pulse sequences, the 1D MQ spectrum has been obtained for the partially deuterated nematic liquid crystal 4-cyano-4'-(*n*-pentyl- d_{11})biphenyl (5CB- d_{11}), which has eight ring protons coupled to each other and yields a rather broad deuterium-decoupled single-quantum spectrum, but well-resolved five-, six-, and seven-quantum spectra (Figure 4).³³ Detailed analyses of these spectra have been carried out to obtain the dipolar couplings between various protons. The two biphenyl rings were either considered equivalent (D_4 symmetry) or inequivalent (D_2 symmetry). While an unequivocal fit was not obtained for either model, the D_4 symmetry resulted in the most physically reasonable

molecular parameters. However, several splittings could not be explained by either of these models or by the effect of strong couplings, and it was suggested that rf inhomogeneity might provide an explanation for the extra splittings not predicted by the D_4 symmetry.³³

3.2.2 Selectivity of Excitation and Detection

Attempts have been made to excite/retain only a few selected orders instead of all orders of MQ, thereby increasing the intensity of the particular order and the resolution of the detected order. Retaining a particular order is rather straightforward by phase cycling the detection pulse (the third 90° pulse) and the receiver or the excitation sequence and the receiver, in a concerted manner.¹² An example is shown in Figure 5.³⁴ The selection of a particular MQ order can also be achieved by using the technique of coherence transfer echo filtering (CTEF). A field gradient pulse of length τ in the MQ evolution period followed by a field gradient pulse of length $n\tau$ during the detection period refocuses only the n th order. This has been demonstrated on hexachloroethane oriented in EBBA.⁴³

A large amount of effort has been made by Pines and co-workers in attempting to excite selectively all the transitions of a particular order using dipolar refocusing.^{26,29,38–40} The introduction of a 180° pulse in the middle of the excitation sequence, along with appropriate phases of the two 90° pulses, yields an even- or odd-order excitation sequence for weakly coupled spins.¹² However, for dipolar-coupled spins,

Figure 3 Two-dimensional multiple quantum spectrum of oriented benzene obtained using the pulse sequence $(90^\circ, \tau, 90^\circ, t_1, 90^\circ, t_2)$, recorded at 200 MHz with a spectral offset of 6 kHz. (Reproduced by permission of Elsevier Science Publishers BV from Drobny²²)

it is possible to reverse the sign of the effective dipolar Hamiltonian by using multiple pulses, allowing one to design pulse sequences for exciting a particular order. The basic building block of the pulse sequence is shown in Figure 6. This block replaces the nonselective excitation sequence $90^\circ - \tau - 90^\circ$. Each sub-block consists of three parts. The first has a sequence of 90° pulses with interval τ , yielding a first-order average Hamiltonian $\hat{\mathcal{H}}_p$, and is applied for a time T .

The second part consists of a delay $\Delta\tau_p$, and the third consists of a sequence of 90° pulses with delays of τ and 2τ , having an average Hamiltonian $-\hat{\mathcal{H}}_p'$ applied for a time T' such that $\hat{\mathcal{H}}_p T = \hat{\mathcal{H}}_p' T'$. Together, these yield the first sub-block, having an average Hamiltonian $\hat{\mathcal{H}}_0$, where the subscript refers to the phase of this sub-block. These sub-blocks are repeated n times, where n is the order to be selected, and the phase is

Figure 4 Multiple quantum proton spectrum of 5CB-*d*₁₁ obtained using the pulse sequence (90°, τ , 90°, $\frac{1}{2}t_1$, 180°, $\frac{1}{2}t_1$, 90°, τ), at 182 MHz. The various multiple quantum orders are separated by TPPI, and the spectrum is the sum of magnitude mode spectra recorded for several values of τ ranging from 0.4 to 1.4 ms. (Reproduced by permission of Elsevier Science Publishers BV from Sinton and Pines²⁷)

Figure 5 Double quantum versus single quantum correlation proton spectrum of 81% randomly deuterated *n*-hexane recorded by the sequence $(90^\circ_\phi, \frac{1}{2}\tau_1, 180^\circ_\phi, \frac{1}{2}\tau_1, 90^\circ_\phi, t_1, 90^\circ_\alpha, \frac{1}{2}\tau_2, 180^\circ_\alpha, \frac{1}{2}\tau_2, t_2)$, recorded at 360 MHz, under deuterium decoupling. The phase ϕ was incremented by 90° while the receiver phase was incremented by 180° . This retains double quantum coherences. Six vertical lines have been drawn at ν_1 frequencies corresponding to double quantum frequencies $2\nu_M, \nu_M+\nu_E, \nu_M+\nu_E, 2\nu_E$, and $\nu_E+\nu_E$. (Reproduced by permission of the American Chemical Society from Gochin et al.³⁴)

incremented each time for the entire subcycle by $\phi = 2\pi/n$. For better selectivity, the whole sequence may be repeated N times, where N may be 4 or 5. The results of such selective excitation are shown in Figure 7. More details about such

Figure 6 Pulse scheme for selective excitation of the n -quantum spectrum of dipolar-coupled spins. The order n is selected by incrementing ϕ in steps of $2\pi/n$. (Reproduced by permission of the American Physical Society from Warren et al.²⁶)

excitations are given by Warren et al.^{26,29} and Drobny et al.⁴⁰ The highest order spectrum of N coupled spins $\frac{1}{2}$ is always a single line, whose position is determined by the sum of the chemical shifts of the coupled spins and is independent of spin-spin and dipolar couplings. Pines and co-workers have demonstrated that the $(N - 1)$ th- and $(N - 2)$ th-order spectra contain enough information to allow a spectral fit by iteration on the dipolar couplings, if there are no chemical shift differences, and, in general, it is possible to derive all the information from high-order MQ spectra that have a finite number of lines to be iterated upon.^{25,28,30,35–40}

Most of the spectra using the above experimental procedures have been recorded using 2D pulse sequences, but recorded in a 1D manner using a single point detection in t_2 . We shall restrict further discussion to 2D spectra.

3.2.3 Simplification of Spectra by Specific and Random Deuteration

As the number of dipolar-coupled spins increases beyond six or seven, the spectra become too complex for analysis by conventional procedures. Specific deuteration, coupled with deuterium decoupling—a straightforward technique for reducing the number of coupled protons—has been used in several cases. The main studies have been carried out on *n*-hexane- d_6 , deuterated at methyl positions, and on 4-cyano-4'-(*n*-pentyl- d_{11})biphenyl (5CB- d_{11}), in which all the aliphatic protons have been deuterated, reducing both to systems of eight coupled protons.^{27,33,35,39} The six- and seven-quantum 2D MQ spectra of *n*-hexane- d_6 (Figure 8) have been used to obtain the various dipolar couplings and their signs to estimate the dynamic molecular structure in the form of conformational probabilities.^{35,39}

Another method of reducing the size of the spin system, but retaining information on dipolar couplings between all the protons of a molecule, is the technique of random deuteration combined with multiple quantum 2D spectroscopy or multiple quantum filtered COSY.^{24,36,44,45} For example, an 81% random deuteration of *n*-hexane, which has 14 protons, yields approximately 6%, 18%, 25%, 25%, 14%, 5%, 3%, 2%,

Figure 7 Four-quantum selective (a) and nonselective (b) MQ spectra of oriented benzene. (Reproduced by permission of the American Institute of Physics from Warren et al.²⁹)

Figure 8 Absolute value six- and seven-quantum versus single-quantum correlation 2D spectrum of *n*-hexane-*d*₆ deuterated at methyl positions obtained by using the same pulse sequence as in Figure 5. The various orders were separated by TPPI using $\Delta\phi = 22.5^\circ$. (Reproduced by permission of Elsevier Science Publishers BV from Gochin et al.³⁵)

and 1% molecules having 0, 1, 2, 3, 4, 5, 6, 7, and 8 protons, respectively.³⁶ Of these, only the one-, two-, and three-proton cases give significant intensity. The one-proton spectra can be easily filtered out using double quantum spectroscopy/filtering. The three- and high-spin spectra are quite low in intensity owing to the large number of lines and large number of possible spin systems. The double quantum filtered COSY (DQFC) spectrum thus contains prominently only the spectra of two coupled spins, and yields square patterns for each of the spin systems.^{34,36} Numbering the carbons as M, E₁, E₂, E₂', E₁', and M' in *n*-hexane, the various two-spin systems will be of the A₂ type for the protons in MM, E₁E₁, E₂E₂, E₂E₂'(*cis*), E₂E₂'(*trans*), E₁E₁'(*cis*), E₁E₁'(*trans*), and MM' positions, and

Figure 9 Double quantum filtered COSY (DQFC) spectrum of 81% randomly deuterated *n*-hexane-*d*_{0.81} obtained using the pulse sequence ($90^\circ_\phi, \frac{1}{2}t_1, 180^\circ_\phi, \frac{1}{2}t_1, 90^\circ_\phi, \frac{1}{2}\tau_1, 180^\circ_\phi, \frac{1}{2}\tau_1, 90^\circ_x, \frac{1}{2}\tau_2, 180^\circ, \frac{1}{2}\tau_2, t_2$), with phase cycling to retain double quantum coherence during the period τ_1 . (a), (b), and (c) show successively expanded regions of the spectrum. The various two-spin systems are identified with square patterns. (Reproduced by permission of Taylor and Francis Ltd. from Gochin et al.⁴⁴)

of AB type for ME₁, ME₂, ME₁', E₁E₂(*cis*), E₁E₂(*trans*), E₁E₂'(*cis*), and E₁E₂'(*trans*) positions. All such spin systems have been readily identified in the DQFC spectrum of 81% deuterated *n*-hexane recorded under deuterium decoupling (Figure 9), and several in the double-quantum 2D spectrum (Figure 5).^{34,36} This yields all the dipolar couplings in *n*-hexane. Detailed analysis of the measured dipolar couplings has been carried out in terms of conformation and orientations of *n*-hexane in the liquid crystal solvent.

Recently, this idea has been extended to a series of *n*-alkanes, from hexane to decane (random deuteration level

of 80–90%), oriented in a nematic liquid crystal.⁴⁴ The DQFC spectrum in each case yields a large number of square patterns, each of which belongs to a two-spin system, yielding the totality of dipolar couplings between pairwise protons in the above molecules. The interpretation of the measured dipolar couplings is complicated, since they are averaged over molecular conformations and orientations sampled by the molecules. Nevertheless, they provide constraints on the time-averaged conformations and orientations of the molecules, which in turn allow an examination of various possible models for the solute–liquid crystal interactions.⁴⁴

DQFC spectroscopy has also been utilized for a study of 78.7% randomly deuterated benzene oriented in a nematic phase.³⁶ Subspectra of three diprotonated and three triprotonated species could be identified in the spectrum. The subspectra were compared with the simulated spectra for various assignments, and the spectral parameters were obtained. A five-quantum versus single-quantum correlation 2D spectrum was also recorded for 34% randomly deuterated benzene. The five-quantum spectrum can be obtained either from fully protonated species or singly deuterated species. The singly deuterated species has only one five-quantum transition, while the fully protonated species has two five-quantum transitions, the correlation of which with various single quantum transitions yields various spectral parameters.³⁶

3.2.4 Application to Chemically Exchanging Systems

Multiple quantum 2D spectroscopy has also been applied to chemically rearranging systems of oriented *s*-trioxane, which undergoes ring inversion, and oriented cyclooctatetracene, which undergoes a bond shift rearrangement.⁴⁶ Two-dimensional MQ–SQ correlation spectra were recorded at various temperatures, from which projected MQ spectra were obtained. The high-order (four and six) MQ spectra are much simpler than the single-quantum spectra, and exhibit characteristic exchange broadening and narrowing effects very similar to the single-quantum spectra. It is much easier to compare the high-order MQ spectra with the simulated spectra, calculated using exact as well as approximate expressions for the dynamic lineshapes, which then yield information on the rates of the dynamic processes. The uses, advantages, and limitations of the technique have been discussed in detail.⁴⁶

4 EXPERIMENTS UTILIZING LONGITUDINAL SPIN ORDER

4.1 Effect of Strong Coupling in NOESY

It is known that each cross-section of the NOESY experiment using the $(90^\circ, t_1, 90^\circ, \tau_m, 90^\circ, t_2)$ sequence is equivalent to a 1D difference NOE experiment in which the spin corresponding to the diagonal peak is selectively inverted at $\tau_m = 0$. It has been shown recently that this equivalence breaks down for strongly coupled spins, resulting in cross peaks in NOESY experiments, even without relaxation.^{47,48} Explicit theoretical calculations have been carried out for an AB spin system, and the results are given in Figure 10.

Calculations have also been carried out for an ABX spin system, showing the existence of cross peaks between

Figure 10 Schematic spectrum of an AB spin system calculated for the NOESY experiment $(90^\circ, t_1, 90^\circ, \tau_m, 90^\circ, t_2)$, with phase cycling to retain longitudinal magnetization during the short period τ_m . The intensities of the 2D peaks are obtained by multiplying the symbols with the 1D intensities indicated on the ω_1 and ω_2 axes. For example, the intensity of the bottom left diagonal peak is given by $-v^4(1+u^4)$, where $u = \cos \theta + \sin \theta$, $v = \cos \theta - \sin \theta$, and $\tan 2\theta = J_{AB}/(\nu_A - \nu_B)$. All cross peaks disappear for weakly coupled spins ($\theta = 0$, $u = v = 1$). (Reproduced by permission of the *Bulletin of Magnetic Resonance* from Christy Rani Grace and Kumar⁴⁸)

all X and AB transitions, even when X is only weakly coupled to AB.⁴⁸ The existence of such cross peaks has been experimentally demonstrated in oriented acetone (Figure 11), where a quantitative fit to the experimental cross sections, after removal of zero quantum interference, has been demonstrated by detailed calculations.⁴⁷ These cross peaks arise owing to the combined effect of strong coupling and the nonlinearity of the rf pulses. In order to examine whether the cross peaks are due to nonlinearity of the second or the third pulse in the NOESY experiment, calculations for the ABX spin system have been carried out for a small-angle second or third pulse. In an ABX spin system, there are two X transitions between pure states. In the experiments with the second pulse being of small angle and the third being 90° , there are no cross peaks from these X transitions to the AB transitions. Similarly, in the experiment in which the second pulse is 90° and the third is of small angle, there are no cross peaks from AB transitions to these X transitions. These observations indicate that the nonlinearity of a pulse is restricted to transitions within a spin or within groups of strongly coupled spins.⁴⁸

4.2 Construction of Energy Level Diagrams

4.2.1 Using NOESY- α, β

In the linear regime, the NOESY- α, β experiment corresponds to the sequence $(90^\circ, t_1, \alpha, \tau_m, \beta, t_2)$, where α is a small-angle pulse and only longitudinal magnetization is retained during the period τ_m . It has been shown recently that, irrespective of the strength of coupling, each cross section of this experiment is equivalent to a 1D difference experiment in which the peak corresponding to the diagonal is selectively inverted at $\tau_m = 0$ and the state of spin system is monitored by the β pulse. If β is also a small-angle pulse then the state of the spin system is measured faithfully. In a coupled spin system, selective inversion of a transition gives rise to a direct population effect on all the transitions that share energy levels with the inverted transition. The transitions that increase or

Figure 11 Phase-sensitive NOESY spectrum of oriented acetone obtained using the pulse sequence ($90^\circ, t_1, 90^\circ, \tau_m, 90^\circ, t_2$), with phase cycling to retain longitudinal magnetization during the short period τ_m ($= 20 \mu\text{s}$). Filled contours represent negative intensity. The various cross peaks here arise mainly owing to the strong coupling effect. decrease in intensity are called progressively or regressively connected to the inverted transition, respectively. Use has been made of this information, without bringing in relaxation (for small values of τ_m), to construct energy level diagrams of oriented molecules.⁴⁹ This experiment is similar to a Z-COSY experiment,⁵⁰ as well as to a large number of difference 1D experiments in which one peak is selectively inverted at a time.

Figure 12 shows the 2D spectrum of oriented acetone recorded using NOESY- α, β for $\tau_m = 10 \mu\text{s}$ and $\alpha = \beta = 14^\circ$. As in COSY- β , the cross peaks here are also only between directly connected transitions within each irreducible representation, with the advantage that the 2D spectrum has pure absorptive lines.⁴⁹ From various cross sections of such spectra, a connectivity matrix is built up by entering (+1), (−1), and 0 for progressively, regressively, and unconnected transitions, respectively. This connectivity matrix is supposed to be symmetric, and its systematic analysis leads to a complete identification of the connected network of transitions, and in turn the complete energy level of a given symmetry.⁴⁹ The well-known problems of zero quantum coherences, which are not cancelled by NOESY phase cycling, also interfere in this experiment, and therefore have to be removed by known procedures.¹² The connectivity information has also been utilized for the analysis of the spectrum of

Figure 12 Phase-sensitive small-flip-angle NOESY (NOESY- α, β) spectrum of oriented acetone for $\alpha = \beta = 14^\circ$ and $\tau_m = 20 \mu\text{s}$, using the sequence ($90^\circ, t_1, \alpha, \tau_m, \beta, t_2$) while retaining only the longitudinal magnetization during the short interval τ_m . Each diagonal peak has cross peaks only to directly connected transitions within the irreducible representation. Filled contours represent negative intensity. cis,cis-mucanonitrile oriented in ZL1-1167, a four-spin system having C_{2h} symmetry.⁵¹

4.2.2 Using Z-COSY

Similar experiments (Z-COSY: $90^\circ, t_1, \alpha, \tau_m, \alpha$) have also been performed on oriented methanol (an A_3B type of spin system) and oriented 1,3-dichlorobenzene (A_2BC). By systematically reducing the flip angle α , the direct progressive and regressive connectivities were identified. Patterns of connectivity were identified with the help of such spectra, which were then utilized for the construction of energy level diagrams. This information was in turn utilized for iteratively obtaining the complete Hamiltonian and its parameters.⁵⁰

5 OTHER STUDIES

There has been an interesting application of near-magic-angle sample spinning combined with 2D NMR (COSY and 2D J -resolved experiments) of substituted benzenes dissolved in lyotropic liquid crystals. The normal spectra of these molecules were too complex to be analyzed. The near-magic-angle spinning simplified the spectrum considerably, and, in addition, the 2D J -resolved spectrum showed well-resolved multiplet patterns for various protons, while COSY helped in identifying the peaks of these protons.⁵²

Another interesting study has been a 2D correlation of the liquid crystal spectrum with the isotropic spectrum by the use of a temperature jump during the mixing period. This allows a straightforward separation of the liquid crystal spectrum into various chemical sites.⁵³ There are several detailed and informative 2D NMR studies of both the spin echo and the correlated type of $I \geq 1$ spins in oriented systems, as well as many 2D NMR studies of liquid crystal molecules with and without magic angle sample spinning. Further, there have been several studies of zero field NMR of molecules oriented in liquid crystal matrices. These studies are discussed in other articles in this Encyclopedia.

1 INTRODUCTION

Chemical exchange, i.e. the transfer of atoms, molecules or molecular groups between two or more different environments or regions, is a phenomenon encountered frequently in studies by NMR of a wide variety of chemical, physical and biological systems. Different environments are usually revealed in NMR experiments through distinct resonance frequencies, spin–spin coupling constants, or relaxation times characteristic of the regions between which chemical exchange takes place. The types of atomic or molecular motion most often investigated on metal surfaces include surface diffusion, adsorption and desorption, exchange between different surface sites or different types of adsorbed species, molecular reorientation, and reorientation of molecular groups.

Because NMR requires at least ca. 10^{18} spins at the surface to be able to detect a signal, single crystal surfaces cannot be studied (10^{15} spins). However, introducing the metal in the form of small particles with diameters in the order of nanometers into porous materials, provides a sufficiently high number of surface sites for adsorption to be studied by NMR. These support materials are mostly oxide compounds like silica, alumina, titania, or zeolites with high internal surfaces of several hundred square meters. At the same time, highly dispersed supported metals, e.g. group VIII elements like ruthenium, rhodium, palladium, osmium, iridium, and platinum, are very often of interest in basic and applied research in catalysis (see also *Supported Metal Catalysts*, and *Adsorbed Species: Spectroscopy and Dynamics*).

Several NMR techniques are available to study exchange phenomena of adsorbed species. Spin–lattice relaxation¹ measurements are useful if chemical exchange dominates as a source for relaxation, or can be separated from other relaxation mechanisms, e.g. relaxation via the conduction electrons of the metal, called Korringa relaxation (see *Electron–Nuclear Hyperfine Interactions*). To be investigated by relaxation measurements, the characteristic time constants of exchange τ_{ex} have to be in the order of 10^{-9} s for spin–lattice relaxation in the laboratory frame to 10^{-5} s for spin–lattice relaxation in the rotating frame.¹ For a review of the relaxation method used to study the dynamics on surfaces we refer the reader to the literature.^{2–4} The analysis of lineshapes or resonance shifts

obtained by conventional NMR techniques are sensitive in the dynamic range of $10^{-6} \leq \tau_{\text{ex}} \leq 10^{-3}$ s. Spin labeling methods extend this range up to more than 10^{-1} s. Two-dimensional NMR techniques, applicable in approximately the same slow dynamic range, are most effective if the exchanging species exhibit separate NMR peaks or if well-defined lineshapes due to anisotropic interactions can be observed.⁵

In the present article the theoretical basis necessary to understand the evolution of nuclear spin magnetization influenced by chemical exchange is outlined briefly. The reader is introduced to spin-labeling and two-dimensional (2D) NMR techniques, which are frequently used to monitor exchange. Finally, experimental examples regarding chemical exchange on metal surfaces are discussed.

2 THEORY OF MAGNETIZATION EXCHANGE

In the following it is assumed that the spatial motion of molecules or atoms can be described classically. If all spin interactions are secular with respect to the Zeeman interaction, i.e., the corresponding interaction Hamiltonians commute with the Zeeman Hamiltonian, then each spin can be considered as being subjected to a local field arising from the environment, superimposed on the external static field. Chemical exchange has the effect of causing random fluctuations of the local field. For example, a nuclear spin situated in a molecule or atom, which jumps randomly between two regions on a surface, such that each region gives rise to a different isotropic resonance shift, experiences a random modulation of its resonance frequency. The influence of such frequency fluctuations upon the NMR lineshape was first treated by Hahn, Maxwell, Gutowsky, McCall, and Slichter.⁶

If the spin Hamiltonian contains nonsecular terms, arising, for example, from J couplings observed commonly in liquids, a quantum-mechanical treatment (spin density matrix formalism) is required.⁷ Splittings due to J couplings are often difficult to detect in NMR studies of adsorbates on metal surfaces because of insufficient spectral resolution, caused by the heterogeneity of the system, leading to distributions of isotropic chemical or Knight shifts, and/or the presence of ‘solid-like’ spin interactions much stronger than J coupling, like chemical shift anisotropy (see *Internal Spin Interactions and Rotations in Solids*) and paramagnetic shifts.

We confine ourselves here exclusively to the case of secular spin interactions, leading to a classical probabilistic model for the magnetization exchange originating from chemical exchange processes. The probabilistic model is commonly represented by a stationary Markov process,^{8,9} allowing the derivation of equations of motion for the nuclear spin magnetization in the form of generalized Bloch equations.^{9–11} The evolution of longitudinal and transversal magnetization components for all regions, between which exchange takes place, are given as a system of coupled differential equations with rate coefficients describing the magnetization exchange process. Solving these equations is a standard problem of analysis and matrix algebra (see Ernst et al.¹¹ and Jeener et al.¹³) and enables explicit calculation of NMR lineshapes.

Figure 1 illustrates the principal effects on the NMR lineshapes originating from magnetization exchange between two regions or sites. Regions A and B, populated by N_A and N_B spins, respectively, are characterized by distinct resonance

Figure 1 (a) NMR lineshape versus $\delta\omega\tau_{\text{ex}}$ for symmetric two-site exchange ($N_A = N_B$). (b) Variation of the resonance frequency in the fast exchange limit as a function of $N_A:N_B$

frequencies ω_A and ω_B , $\delta\omega = \omega_B - \omega_A$. This difference of resonance frequencies may be caused by different isotropic chemical or Knight shifts. In the slow exchange limit, $\delta\omega\tau_{\text{ex}} \gg 1$, where τ_{ex} is a characteristic time constant for the exchange process, two separate lines appear in the NMR spectrum [Figure 1(a)], which become broadened with decreasing $\delta\omega\tau_{\text{ex}}$, and coalesce to a single broad line at $\delta\omega\tau_{\text{ex}} \approx 1$. With $\delta\omega\tau_{\text{ex}}$ decreasing further, only one single ‘exchange-averaged’ narrow line is observed (fast exchange limit, $\delta\omega\tau_{\text{ex}} \ll 1$). The spectra in Figure 1(b) were calculated for the fast exchange limit varying the ratio $N_A:N_B$ of spin numbers in regions A and B, leading to a variation in the resonance frequency of the exchange averaged resonance line as well as to a broadening for values of $N_A:N_B$ near unity. The dependence of the resonance shift δ on N_A and N_B can be expressed for the fast exchange limit as the weighted average:

$$\delta = \frac{N_A}{N_A + N_B} \delta_A + \frac{N_B}{N_A + N_B} \delta_B \quad (1)$$

of the individual resonance shifts δ_A and δ_B . The mathematical formalism to calculate the above lineshapes is still applicable if anisotropic interactions, to be described by interaction tensors, e.g. chemical shift anisotropy, are present. However, because of the random spatial orientations of the principal tensor axes in a powder sample, the resulting orientation dependence of the resonance frequencies has to be taken into account to obtain the lineshape.¹⁰

3 ADVANCED NMR TECHNIQUES TO MONITOR EXCHANGE

As shown above, no significant changes of the one-dimensional NMR lineshapes or frequencies occur in the slow exchange limit. More advanced NMR techniques are available to detect such slow exchange processes.

3.1 Spin Labeling by Selective Excitation

The idea of spin labeling is based on the fact that the actual chemical exchange process, being in thermal equilibrium, causes an exchange of spin magnetization.¹² The latter is initially prepared by irradiation of rf pulses to be in nonequilibrium. The irradiation of an rf pulse, or a sequence of rf pulses affects only spins resonating within the spectral excitation window defined by the Fourier transform of the pulse sequence [Figure 2(a) and (b)]. Although this Fourier picture is only an approximation when selective saturation or inversion is considered,¹² it is a useful qualitative description. Denoting the length of a single rf pulse or the total duration of a pulse sequence by τ_p , the excitation width in the frequency domain is proportional to $1/\tau_p$, with the rf carrier frequency in the center of the excitation window. The irradiation of either a long pulse of low rf power or a sequence of strong, but very short pulses, as indicated in Figure 2(a), allows selective excitation of spins. The pulse sequence can be adjusted to act in total like a 90° pulse (selective saturation) or a 180° pulse [selective inversion, illustrated in Figure 2(c)]. Therefore, spins within the spectral window can be labeled, for example, by inversion of their magnetization, while spins which resonate outside the window remain unaffected. If a pulse sequence is used, excitation sidebands also occur [Figure 2(b)]. During a subsequent time interval τ_m [Figure 2(a)] the spin system is allowed to undergo free time evolution. The NMR signal is detected finally by a short (nonselective) 90° pulse. Selective excitation (saturation or inversion) of a narrow frequency band within a broad NMR line, for example, caused by chemical shift anisotropy, is called ‘spectral hole-burning’. If chemical exchange is present, the labeled spins may change their resonance frequencies resulting in a redistribution of spin

Figure 2 Spin labeling by selective excitation: (a) pulse sequence, (b) Fourier transformation of the train of equidistant pulses, and (c) NMR spectrum showing a selectively inverted line

magnetization toward spectral regions outside of the selected window. The recovery of the spectral hole, or of the intensity of an inverted single resonance line, can be measured as a function of the recovery time τ_m to reveal the kinetics of a chemical exchange process.

Magnetization recovery is also caused by spin–lattice relaxation of the spin magnetization. Only exchange processes with a characteristic time τ_{ex} shorter than the spin–lattice relaxation time T_1 can be observed. Spin-labeling becomes ineffective if the chemical exchange process is faster than the spin-labeling process itself (characteristic time constant τ_p). Thus accessible by spin-labeling techniques are exchange processes within a timescale $\tau_p < \tau_{ex} < T_1$.

3.2 Two-Dimensional Exchange NMR

Two-dimensional exchange NMR techniques¹³ are based on the idea of measuring the frequency of spin magnetization components at two different times during the NMR experiment. After the initial preparation period, which consists of a waiting period to allow equilibration of the longitudinal magnetization and irradiating the first $\pi/2$ pulse, transversal magnetizations are present, oscillating with frequencies ω_A and ω_B during the time t_1 [evolution period, Figure 3(a)] corresponding to spins located in regions A and B. A second $\pi/2$ pulse converts the magnetization present at time t_1 into longitudinal magnetization. During the mixing time τ_m (usually much longer than the time t_1) slow chemical exchange leads to a random modulation of the precession frequencies of the two magnetization components M_{zA} and M_{zB} . Spins which were resonating at ω_A at the end of the period t_1 may resonate at either ω_A or ω_B at the end of the mixing period τ_m (and vice versa). The NMR signal is detected after the final $\pi/2$ pulse during the time period t_2 . Repeating the experiment by incrementing the time t_1 in small steps, yields a two-dimensional time-domain interferogram which after 2D Fourier transformation¹¹ with respect to t_1 and t_2 gives the 2D NMR spectrum $S(\omega_1, \omega_2)$. If exchange occurs between A and B, cross peaks are observed, labeled $A \rightarrow B$ and $B \rightarrow A$ in Figure 3(b), in addition to main peaks A and B located along the principal diagonal.¹⁴

4 CHEMICAL EXCHANGE OF ADSORBED SPECIES ON METAL SURFACES: EXAMPLES

Chemical exchange phenomena at or near metal surfaces observed by NMR encompass a wide dynamical range extending from the fast exchange limit ($\tau_{ex} < 10^{-5}$ s) to extremely slow processes ($\tau_{ex} > 1$ s). The details of the chemical exchange processes might be quite different, originating, for example, from adsorption or desorption, exchange between different surface sites, exchange between different populations of adsorbed species or surface diffusion.¹⁵

4.1 Exchange Dynamics of CO Adsorbed on Metals

Carbon-13 spin labeling techniques have been applied by Duncan, et al.¹⁶ to elucidate in detail surface diffusion of

Figure 3 (a) Basic 2D NMR pulse sequence to monitor exchange. (b) Schematic representation of a 2D NMR spectrum for exchange between two sites A and B

CO and slow exchange between different carbonyl species adsorbed on rhodium. Molitor and Apple¹⁷ performed ^{13}C NMR powder lineshape calculations for reorientating dicarbonyl groups bonded to rhodium. Surface diffusion of CO chemisorbed on palladium has been investigated by means of ^{13}C relaxation measurements and lineshape analysis.¹⁸

4.2 Fast Exchange of Hydrogen on Metal Surfaces

Proton NMR peaks of hydrogen interacting with metal surfaces are commonly shifted to lower frequency (i.e. upfield) due to the Knight shift interaction and reveal relatively small linewidths, especially at elevated external H_2 pressures and temperatures above room temperature, indicating high intrinsic mobility. Variations of the resonance frequency of ^1H NMR peaks, attributed to hydrogen on the metal surface, versus pressure (i.e. changing the number of hydrogen atoms or molecules on the surface) may be caused by at least two different mechanisms: (i) fast exchange between surface environments with different Knight shifts [as illustrated in Figure 1(b)]; and (ii) by a variation of the Knight shift interaction itself, because the latter may be a function of the surface coverage. As pointed out above, fast exchange between two regions leads to an averaged NMR line representing hydrogen in both regions. Variation of the resonance shift

Figure 4 ^1H NMR resonance shift δ for hydrogen adsorbed on ruthenium–copper bimetallic particles and fraction X_{Ru} of surface ruthenium as a function of the copper content

with pressure, or coverage, has been observed quite frequently by ^1H NMR¹⁹ or ^2H NMR²⁰ for hydrogen adsorbed on various metals like platinum, rhodium, and ruthenium (see also refs. 18–20 and 23–24 given in Wu et al.¹⁹). The resonance shift variation of hydrogen due to fast exchange between different surfaced regions has been used to monitor the surface composition of bimetallic particles.²¹ In this case hydrogen atoms are rapidly exchanging between sites on the bimetallic particle surface, composed of sites with different Knight shifts for adsorbed hydrogen. As shown in Figure 4, on particles consisting of pure ruthenium, hydrogen resonates at -62 ppm [to low frequency relative to tetramethylsilane (TMS)]. Increasing the total copper content of the sample leads to a systematic decrease of the ^1H NMR resonance shift δ , approaching asymptotically the value of -49 ppm for a copper content near 80 at%. This shift value is regarded as the resonance shift for hydrogen adsorbed on copper sites of ruthenium–copper bimetallic particles. Applying equation (1) inserting $\delta_{\text{Cu}} = -49$ ppm and $\delta_{\text{Ru}} = -62$ ppm, the fraction $X_{\text{Ru}} = N_{\text{Ru}}/(N_{\text{Ru}} + N_{\text{Cu}})$ of ruthenium atoms exposed at the particle surface can be determined (see Figure 4). Therefore, in this example the ^1H NMR resonance shift provides a sensitive measure for the composition of the surface.

4.3 Slow Exchange Between Different Hydrogen Populations on the Metal Surface

Figure 5(a) shows an in situ ^1H NMR spectrum of silica supported ruthenium, obtained at $T = 400$ K and at an external H_2 pressure of 300 Torr.²² Two distinct resonance lines (denoted as α and β) are observed, originating from two different hydrogen species, characterized by different heats of adsorption. The 2D exchange NMR spectrum [Figure 5(b)] was obtained by the pulse sequence illustrated in Figure 3(a). The cross peaks reveal a slow exchange process within the timescale of the experiment, given by the mixing time $\tau_{\text{mix}} = 2$ ms, occurring between α and β hydrogen, but there is no exchange within this timescale between the α or β species and the hydrogen residing on the silica support. Spin

Figure 5 (a) Conventional ^1H NMR spectrum of silica supported ruthenium. (b) 2D exchange NMR spectrum at $T = 400$ K and external H_2 pressure $p = 300$ Torr

labeling of one of the two spin species, α or β , by selective excitation (Figure 2) allows the determination of the average time constant, $\tau_{\text{ex}} = 700 \mu\text{s}$, for the magnetization exchange between α and β hydrogen.

1 INTRODUCTION

Surfactants are molecules with two distinctively different parts, one of which is hydrophilic and one which is hydrophobic. This feature of surfactants determines their properties in aqueous or oleic solutions. At low enough concentrations they form molecularly dispersed solutions. As the concentration is increased, they self-assemble into aggregates at a rather well-defined concentration, which is termed the *critical micellar concentration* (cmc) on account of the fact that the aggregates formed are termed *micelles*. As the concentration of surfactant is further increased, the aggregates crystallize into liquid crystalline phases with long-range order, the structures of which may vary rather substantially. The addition of a third component, giving rise to a water–oil–surfactant (where ‘oil’ is taken to be a generic term for an oleic component) system, results in an amazingly rich phase behavior, involving both liquid crystalline phases and liquid solution phases.

The present contribution will be concerned with the characterization by means of NMR techniques of two particular types of liquid solution of surfactant, the first being micellar solutions and the second being microemulsions. Having said this, we run into a problem of definition. How do we decide whether a particular solution belongs to one of these classes or perhaps to yet another class of solutions? Commonly, microemulsions are defined as thermodynamically stable solutions containing a surfactant (where ‘surfactant’ is a generic term for a single surfactant or mixtures of different amphiphilic molecules), water and oil. We shall adhere to this definition. Consequently, a micellar solution is one containing a surfactant and water (possibly with added salt) or oil, while the addition of oil or water to a micellar solution turns it into a microemulsion. Possible ambiguities of these definitions will be pointed out as we go along. [The name ‘microemulsion’ is somewhat unfortunate as it implies that the structure in the solution is one of discrete droplets of either water in oil (W/O) or oil in water (O/W). This is only partly true, as a rich variety of structures can indeed be found in addition to these two droplet structures. The literature is abundant with contributions which ignore this fact and only treat the two droplet structures.]

Studies of surfactant solution systems have had a central place in physical chemistry ever since the pioneering work of McBain at the beginning of this century,^{1–4} not least due to

the fact that these systems have important roles in a variety of applied processes. Questions asked pertain to the structure of the aggregates formed as well as the properties on a molecular level of the molecules comprising the systems.

It is fair to state that NMR has played a central role as a tool in tackling these questions, and much of our current understanding of surfactant solutions derives from NMR studies where two NMR methods have been especially important. The first of these is NMR relaxation studies, which have evolved to become an indispensable tool in studies of liquid surfactant solutions. The second one is measurements of self-diffusion coefficients by means of pulsed field gradients (PFG), an experiment which yields direct and easily interpretable information regarding many different aspects of surfactant solutions. In fact, our present understanding of the structure in microemulsions is to a large extent derived from PFG work in combination with various scattering approaches.

In the present article we discuss the two NMR approaches and describe applications which we consider to be those where NMR has contributed significantly to our present understanding of liquid solution phases of surfactants.

2 SELF-DIFFUSION STUDIES

Measurements of self-diffusion coefficients by means of PFG techniques have evolved to become one of the most important tools in the characterization of liquid surfactant systems. There are essentially two reasons for this, one of which has to do with the measuring technique itself. Thus the PFG approach offers a convenient method of determining self-diffusion coefficients. The technique is outlined in another article in this Encyclopedia (see *Diffusion Measurements by Magnetic Field Gradient Methods*) and has also been described in a number of review articles.^{5,6} Thus we shall not dwell on the technical aspects here. Suffice is to say that the technique requires no isotopic labeling (thus avoiding possible disturbances due to addition of probes); furthermore, it gives component resolved diffusion coefficients with great precision in a minimum of measuring time.

The second reason for its success rests on the fact that the method monitors transport over macroscopic distances (typically of the order of micrometers), and therefore the determined diffusion coefficients reflect aggregate sizes and obstruction effects, yielding information which is easily interpretable in terms of the microstructure of surfactant solutions. The fact that the information is obtained without the need to invoke complicated models, as is the case in the NMR relaxation approach, is particularly important. In this context it should be stressed that the PFG approach measures the self-diffusion rather than the collective diffusion coefficient.

The foundation for the use of NMR to monitor diffusion was laid in 1950 in the seminal paper by Hahn.⁷ Another milestone occurred in the mid-1960s when Stejskal and Tanner demonstrated,⁸ following a suggestion by Douglass and co-workers,⁹ the use of pulsed gradients. Finally, towards the end of the 1960s the method became component resolved when the FT approach was introduced.¹⁰

In its simplest version, the method consists of two equal and rectangular gradient pulses of magnitude g and length δ , sandwiched on either side of the 180° rf pulse in a simple Hahn

echo experiment. For molecules undergoing free (Gaussian) diffusion characterized by a diffusion coefficient of magnitude D , the echo attenuation due to diffusion is given by^{8,11}

$$I(\Delta, \delta, g) = I_0 \exp \left[-\gamma^2 g^2 \delta^2 \left(\Delta - \frac{\delta}{3} \right) D \right] \quad (1)$$

where Δ represents the distance between the two gradient pulses, γ is the magnetogyric ratio of the monitored spin, and I_0 denotes the echo intensity in the absence of any field gradient. By varying either g , δ , or Δ (while at the same time keeping the distance between the two rf pulses constant), D can be determined by fitting equation (1) to the observed intensities.

In the following we use some illustrative examples to show how the PFG approach can be used to obtain information on surfactant solutions.

2.1 Micellar Solutions

2.1.1 The Micellization Process

The PFG method provides a unique way of investigating the process of micellization. The approach is based on the fact that the observed surfactant self-diffusion rates constitute a population weighted average between micellized and monomeric surfactant. This follows since the surfactant lifetime in the micelle is short on the relevant NMR timescale (which is essentially Δ in equation (1), and thus typically around 100 ms). Thus the observed surfactant diffusion coefficient is given by

$$D_{\text{obs}} = p_{\text{mic}} D_{\text{mic}} + (1 - p_{\text{mic}}) D_{\text{free}} \quad (2)$$

where D_{mic} and D_{free} represent the diffusion coefficients of micellized and free surfactant, respectively, and p_{mic} is the fraction of micellized surfactant. Equation (2) can be rearranged to

$$p_{\text{mic}} = \frac{D_{\text{free}} - D_{\text{obs}}}{D_{\text{free}} - D_{\text{mic}}} \quad (3)$$

Clearly, one can obtain the degree of micellization as a function of total surfactant concentration from the concentration dependence of D_{obs} , provided that D_{free} and D_{mic} are known. D_{free} can be obtained from measurements below cmc, while D_{mic} can be obtained from the diffusion coefficient of a hydrophobic probe which is solubilized into the micelles and for which p_{mic} is unity. A suitable probe is hexamethyl-disilane (HMDS) which, if it is added in small amounts (on average one probe per micelle is a recommended concentration), seems only negligibly to disturb the micelles (although for some systems it should be used with some care¹²). Once D_{free} and D_{mic} are known, p_{mic} is obtained without the need to invoke any model for the micellization process. For ionic surfactants the same approach can also be used to obtain the degree of counterion association with the micelles, provided that the counterions contain nuclei suitable for PFG work, which is the case for surfactants with organic counterions.

The result of the approach outlined above is shown in Figure 1, in which a textbook example of the micellization

Figure 1 Self-diffusion data for the surfactant ion ($\text{C}_{10}\text{H}_{21}\text{ND}_3^+$) ($\diamond$) and counterion ($\text{CHCl}_2\text{COO}^-$) ($\blacklozenge$) of a cationic surfactant with an organic counterion. Also given are the diffusion coefficients of the micelles ($\square$), as measured by solubilizing a small amount of HMDS into the micelles. By applying the two-site model given by equation (3) one can estimate both the fraction of micellized surfactant and the degree of counterion binding to the micelles from the diffusion coefficients. For instance, at 140 mM total concentration of surfactant $p_{\text{mic}} = 0.8$, while the degree of counterion binding (defined as the ratio of the concentration of micelle associated counterions to the concentration of micellized surfactant cations) is 0.8. (Data from Jansson and Stilbs.¹³)

process is presented. Data are obtained for a system with an organic counterion.¹³ It is difficult to conceive of any other method that would give the same richness of detail concerning the micellization process. Data such as those presented in Figure 1 have been instrumental in testing various models for describing the micellization process. For instance, approaches based on the Poisson–Boltzmann equation have been very successful in rationalizing the process of micellization for ionic surfactants.^{14,15}

2.1.2 Micellar Size and Structure

Questions pertaining to micellar size and structure may be tackled in two ways by means of PFG studies. The first concerns the measurement of self-diffusion of water (or other small molecules) in the system. Any aggregate present obstructs the diffusion of the water and, as the degree of obstruction depends on the volume fraction of the particles present as well as their geometry, information concerning the latter may be obtained. The mathematical description of such obstruction effects was worked out by Jönsson et al.,¹⁶ who presented results for spheres, prolates, and oblates of different sizes and solution volume fractions.

The other approach to investigating micellar structure is based on Einstein's law, in which the (micellar) diffusion coefficient is related to the frictional factor f through

$$D = \frac{k_B T}{f} \quad (4)$$

where k_B is the Boltzmann constant, and T is the absolute temperature.

The friction coefficient depends on the geometry and size of the diffusing particle as well as on the solvent viscosity η . Expressions relating f to the dimensions exist for several

Figure 2 Micelle hydrodynamic radii for two concentrations of $C_{12}H_{25}(OCH_2CH_2)_5OH$ [(●) 2.73 wt%, (○) 0.92 wt% surfactant] and $C_{12}H_{25}(OCH_2CH_2)_8OH$ [(■) 3.06 wt%, (□) 1.02 wt%]. (Data from Nilsson et al.^{18,19})

different geometries, the simplest being that for a sphere of hydrodynamic radius R_H , which is:

$$f = 6\pi\eta R_H \quad (5)$$

For cases where the geometry is not known, one often uses equation (5) and computes a hydrodynamic radius, on the assumption that the diffusing species is a sphere. An example of this approach is shown in Figure 2, which gives the hydrodynamic radii for micelles formed by nonionic surfactants of the oligo(ethylene oxide) type as a function of temperature. Questions pertaining to the aggregate growth as a function of temperature and concentration in these systems have been the subject of rather lively discussion over the years.¹⁷ Clearly, data such as those presented in Figure 2 are important in this context.^{18–20}

Although the method outlined above is certainly useful, one should be aware of the limitations inherent in the approach. First, equations (4) and (5) assume infinite dilution. As micelles are self-assembled units, one must be aware of the fact that dilution may change their properties. At higher concentrations particle–particle obstruction effects become important, and these must be taken into account.^{21,22}

2.2 Microemulsions

Microemulsions are defined as thermodynamically stable systems containing an oleic solvent (in most basic research a simple hydrocarbon is used), a hydrophilic solvent (most often water or brine), and a surfactant (which can be a combination of several amphiphilic molecules). For weakly amphiphilic molecules the system is molecularly dispersed; this will not be discussed here.

Of particular interest are systems in which small amounts of surfactant may bring equal volumes of oil and water into solution. This can be achieved with less than 1% surfactant, and such systems are usually termed ‘balanced’.²³ In many of these systems one may vary the oil to water volume ratio extensively without ever leaving the one-phase microemulsion

Figure 3 Phase diagram of an alkylpolyglucoside/cosurfactant/water/cyclohexane system at 25 °C with a total surfactant + cosurfactant concentration of 4 wt%. The number of phases present in the various regions of the phase diagram is indicated (for example, the one-phase microemulsion is denoted by 1Φ). (Reproduced with permission from Fukuda et al.²⁴)

region. This is achieved by varying some parameter. Such a parameter is constituted by the temperature in the case of nonionic surfactants of the C_xE_y type, the salinity of the water for ionic surfactants, and the cosurfactant/surfactant ratio in a mixed surfactant system. An example of such behavior is shown in Figure 3, where a recently compiled phase diagram for an alkylpolyglucoside surfactant is displayed. In this case it is the proportion of the cosurfactant (which is a branched alkyl glycerol monoether) in the surfactant mixture which was varied.²⁴

It is a considerable challenge to model such a system, and a prerequisite for such an endeavor is the availability of structural information. It is perhaps in this context that the PFG approach has achieved its most spectacular successes, not least due to the fact that very few other methods can yield such information for microemulsions. How then do we infer structural information from self-diffusion coefficients which are dynamic quantities? The basis of the approach is the fact that the mean distance traveled by the molecules is of the order of $\sqrt{\Delta D}$, which quantity is of the order of micrometers for low molecular weight liquids. Thus any obstruction effects or confinement to droplets of colloidal dimensions affects the diffusion coefficient.

Broadly speaking, one can differentiate between a microstructure of closed particles, whether they are normal (enclosing the oil component) or reversed (enclosing the water), and a microstructure which is bicontinuous. The latter term is often used without being properly defined. We shall take it to imply that a large fraction of both the oil and water molecules exists in domains which span macroscopic distances in three dimensions.

For the case of discrete particles, the continuous phase displays a diffusion behavior similar to that of the neat liquid. There will be solvation effects, i.e. some of the continuous solvent may be associated with the surfactant and, as a consequence, will have an altered diffusional behavior. However, for low surfactant concentration this effect is negligible. Thus any reduction in the reduced diffusion coefficient for the continuous solvent (in PFG studies of microemulsions one preferably reports the reduced diffusion

coefficient, defined as D/D_0 , where D_0 is the bulk diffusion coefficient of the neat liquid at the same temperature) can be attributed to particle obstruction effects (see above). If both the dispersed phase and the surfactant have negligible solubility in the continuous phase, their diffusion is given by the particle diffusion, and so both have the same diffusion coefficient, the value of which can be used to estimate the size of the diffusion particle from equation (4), while the concentration dependence of the diffusion coefficient can be used to infer information about the interaggregate interactions.²²

Turning to the bicontinuous case we note first that both the water and the oil component diffuse rapidly. Careful PFG work using mixtures of oil has revealed that the diffusion process of the oil component is very similar to the diffusion in neat oil.^{25,26} The same holds for the water component.²⁷ This is an important observation, which implies that any reduction in the reduced diffusion coefficient can be attributed to the obstruction effects due to the presence of the surfactant film. Effects such as exchange between droplets and fusion–fission processes cannot explain the rapid oil and water diffusion. Any structural model of microemulsions must not be at variance with this statement. It should be emphasized that, at present, the PFG method is the only way in which bicontinuity may be proved or disproved. Two-dimensional images cannot prove bicontinuity, since it cannot exist in two dimensions.²⁸

Let us now investigate whether the diffusion data for the system in Figure 3 is in line with this reasoning. Figure 4 shows the reduced diffusion coefficients for the water and oil components in the system shown in Figure 3 as a function of the volume fraction of hydrocarbon in the solvent mixture (Φ_{oil}). The data in Figure 4 are typical for microemulsions where the oil content can be varied continuously from no oil to pure oil. Thus the water and oil component diffusion changes continuously from rapid to slow as the fraction of each component is decreased, and the plots of the reduced diffusion coefficients versus the volume fraction of oil in the solvent mixture show a rather characteristic ‘sigmoidal’ curve for both components. At equal volume fractions of oil and water the curves intersect, and the value of both reduced diffusion

Figure 4 The relative self-diffusion coefficients of water ($\diamond$) and hydrocarbon ($\bullet$) as a function of the volume fraction, Φ_{oil} of hydrocarbon in the solvent mixture, for microemulsions formed in the alkylpolyglucoside/cosurfactant/water/cyclohexane system, the phase diagram of which is shown in Figure 3. (Data from Fukuda et al.²⁴)

coefficients is around 0.6 at the point of intersection. In line with the discussion above, this points to discrete particles at low and high values of Φ_{oil} and a bicontinuous structure in between. Based on the information inherent in PFG data such as those presented in Figure 4, how should we picture the bicontinuous microemulsions?

A most fruitful way of looking at these phases is due to Scriven²⁹ who proposed the idea that the structure could be described as a melted liquid crystalline cubic phase, for which the structure is known on account of the scattering studies that can be performed on these systems [cubic phases come in two varieties (discrete and bicontinuous); Scriven had the latter class in mind]. These are formed by two interwoven subvolumes of the same material (polar or nonpolar), which are separated by a film of the opposite material. This dividing film is described as a ‘minimal surface’, having zero mean curvature.

Now, allow this structure to melt, so that the long range order is lost, but locally the structure is retained. When the material on both sides is equal, L_3 phases or bicontinuous micellar solutions (see below) are formed, and the dividing film is a bilayer, while for the case where the two subvolumes are not equal, microemulsions are formed. For this case the dividing film is a monolayer, with a curvature towards the oil or water depending on the volume fraction of the two components.

In an important contribution, Anderson and Wennerström³⁰ have computed the obstruction effect for components in the subvolumes and for components diffusing along the dividing surface. Indeed, these workers found that the reduced diffusion coefficient for a bicontinuous microemulsion with roughly equal oil and water volume fractions is around 0.6, giving further credence to Scriven’s suggestion.

Finally, we note that, when measurements are possible, the value of the surfactant self-diffusion coefficient often displays a maximum with respect to changes in the solvent composition at equal oil and water volume fractions. This observation is more difficult to interpret in terms of a particular microstructure, owing to the difficulties of finding a suitable reference value for the lateral diffusion coefficient for the surfactant along the surfactant film, but it does indicate that the surfactant is diffusing over surfaces that extend over several micrometers with only minor disturbances for diffusions. Consider, for example, the case of a sodium dodecyl sulfate (SDS) microemulsion,³¹ where D for the surfactant was found to be $1.5 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ at 27°C , a value which is in good agreement with the values found for lateral diffusion of SDS over a micellar surface of spherical³² ($D = 1.0 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ at 30°C) and cylindrical³³ ($D = 1.69 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ at 30°C) geometry, where the diffusion is indeed unhindered.

2.3 L_3 -Phases and Bicontinuous Micellar Solutions

The properties of L_3 phases and bicontinuous micellar solutions have been discussed extensively, and they constitute an illustrative example of the power of the PFG method in unravelling solution structure. Both types of solution have a connected structure, and again a fruitful starting point is the (known) structure of the cubic phases. If a cubic phase is diluted with the material of the subvolumes, an L_3 phase

Figure 5 Variation in the reduced water diffusion coefficient with the volume fraction of surfactant in the L_3 ($\diamond$) and cubic ($\blacklozenge$) phases formed in the AOT/water/NaCl system. (Data from Balinov et al.³⁴)

(sometimes known as L^* or ‘sponge’ phase) is formed, while dilution with the material of the dividing film gives rise to a bicontinuous micellar solution. Let us consider the L_3 phase formed in the sodium bis(2-ethylhexyl)sulfosuccinate (AOT)/brine system. In this system, the L_3 phase is in equilibrium with a bicontinuous cubic phase via a two-phase region.³⁴ Figure 5 gives the reduced diffusion coefficients for the water as a function of the surfactant volume fraction Φ_s in both the L_3 and the cubic phase.

There are two noteworthy features of the data shown in Figure 5. First, there is a continuous change in D/D_0 with Φ_s over the two-phase area between the L_3 and cubic phases. Secondly, at high dilution, a limiting value of D/D_0 of around 0.65 is obtained. The first observation indicates that the microstructures in the two phases are similar, since the translational diffusion of water reflects the microstructure of the solution. The second point can be used to infer information about the microstructure in a slightly more rigorous way. Consider a structure of discrete particles. According to the obstruction factors derived by Jönsson et al.,¹⁶ the only geometry that would give rise to a reduction in D/D_0 from 1 to 0.65 would be large disks with an axial ratio in excess of 100:1. This is not in agreement with the surfactant diffusion, which, for the case of disks, implies an axial ratio of 12:1. Thus we are forced to think of alternative microstructures. Following the suggestion inherent in the first feature of the data in Figure 5, i.e. that the microstructures are similar in the L_3 and cubic phases, let us consider the case of a bilayer continuous structure. As noted above, this case has been treated by Anderson and Wennerström,³⁰ who obtained a value of 0.65 for the reduced diffusion coefficient for the solvent diffusion at low volume fraction of bilayer (in fact, for an infinitely thin multiply connected bilayer, the limiting value is $\frac{2}{3}$, on account of the dimensionality of the bilayer). Moreover, by analyzing the dependence of D/D_0 on Φ_s , information can be obtained regarding the coordination number of the obstructing surface.³⁵

The analysis of the bicontinuous micellar solution structure as based on PFG data follows the same approach as the one described above. Readers interested in this particular micellar solution are referred to the paper by Monduzzi et al.³⁶

Figure 6 A ^1H NMR FT PFG experiment at 100MHz on the solubilization of neopentanol into dodecyltrimethylammonium chloride micelles (solvent D_2O). The degree of solubilization is obtained directly from the evaluated D values for neopentanol in the micellar solution and in an aqueous solution [see equation (3)]. The value for the micellar diffusion coefficient, which is obtained from a small amount of solubilized tetramethylsilane (TMS), is also needed. The gradient current was varied linearly between successive spectra, which were obtained at fixed intergradient (Δ) and rf pulse (τ) intervals

2.4 Solubilization

As a final illustration of the power of the PFG approach, we consider the topic of solubilization. By ‘solubilization’ we mean the incorporation of molecules which are not water soluble into the micellar subvolume of a micellar solution. An important question pertaining to the phenomenon of solubilization concerns the degree of partitioning between the micelles and the water. This question is related to that pertaining to the micellization process (see above), and the same approach used to study that process can be used to investigate solubilization. Thus the degree of solubilization p can be determined by measuring the diffusion coefficient of the solubilize in the absence and presence of micelles, and determining the diffusion coefficient for the micelle (using the approach outlined above) by using equation (3). From the volume or weight fraction of the micellar subvolume and the value of p , one can then determine the desired partition coefficient. A typical PFG solubilization experiment is shown in Figure 6.³⁷

There are several advantages of the PFG approach as compared with other techniques for studying solubilization. The experiment is simple as well as selective. The latter point is particularly important, as one can determine the solubilization of several different solubilizes simultaneously, and each individual value of p can be determined. The presence of impurities is normally not a problem. The quantity p is well defined and easily interpreted. Finally, by measuring the surfactant diffusion one can independently check whether the micelles as such are altered by the presence of solubilizes. Clearly, the whole topic of solubilization becomes somewhat less meaningful if one does not have control over the state of the micelles.

3 RELAXATION STUDIES

NMR relaxation has proven to be a useful experimental technique for studying surfactant aggregation in liquid solutions

and liquid crystals.^{20,38–40} The experiment yields information on the local dynamics and conformational state of the surfactant hydrocarbon chain and has demonstrated the liquid-like interior of surfactant micelles. However, the main purpose of NMR relaxation studies of isotropic micellar solutions and microemulsions has been to study properties such as the aggregate size.

The reorientation dynamics of aggregated surfactant molecules, which are discussed in more detail below, are characterized by the fact that they locally have a preferred orientation, forming essentially a monomolecular film of oriented molecules. Locally, surfactant molecules undergo rapid internal motions, such as *trans*–*gauche* isomerizations in the hydrocarbon chain. These motions are, due to the preferred orientation, slightly anisotropic. The situation can be pictured as the polar headgroups being anchored at the polar–apolar interface, leaving room for dangling motions of the hydrocarbon chains, with certain restrictions on the number of conformations due to packing constraints in the film. In isotropic solutions the residual interaction or anisotropy is further averaged by the thermal tumbling of the aggregates in combination with the diffusion of surfactant molecules within the curved surfactant film.

NMR spectra from surfactants in micellar solutions and microemulsions are generally in the motional narrowing regime, and the spin dynamics are characterized by well-defined relaxation times. Exceptions can be found in solutions of very long ($>10^2$ nm) wormlike cylindrical micelles where the large size in connection with steric overlap gives rise to a very slow (about 10^{-4} s) aggregate reorientation.^{41,42} On the other hand, the dynamics are typically outside the extreme narrowing regime, and one often observes $R_2 \gg R_1$, where R_1 and R_2 are the longitudinal and transverse relaxation rates, respectively. Micellar aggregates reorient on a timescale of 10^{-9} s or slower. Thus, at conventional magnetic field strengths, the essential information on the surfactant aggregates is stored in the transverse relaxation rate R_2 .

A hydrocarbon, typically an alkyl chain of 12–16 carbon atoms, constitutes the major part of surfactant molecules, offering ^1H and ^{13}C nuclei for NMR studies. Being spin- $\frac{1}{2}$ nuclei, the relaxation is mainly due to dipole–dipole interactions (although chemical shift anisotropy and scalar interaction can sometimes be important in the case of ^{13}C). The easy access and the relatively high sensitivity (which was particularly important in early CW NMR studies) has made ^1H NMR (in particular bandwidth measurements) studies particularly popular. Micellar growth can easily be studied qualitatively by monitoring the bandwidth of aliphatic ($-\text{CH}_2-$) protons in the spectrum. Quantitative analysis is, however, complicated by the coupling of the various protons having locally different motional characteristics along the alkyl chain. In an alkyl chain of, say, 16 carbon atoms, the protons constitute a coupled spin system of approximately 2^{16} spin states, which can have a broad spectrum of transition rates, resulting in significant deviations from a Lorentzian bandshape of the CH_2 resonance.^{41,43} This complexity can, however, be turned into an advantage in that it allows for a continuum description of the transition rate spectrum. The ^1H bandshape problem was analyzed by Wennerström et al.^{41,43} within the two-step formalism (see below), and quantitative ^1H bandshape analyses have been performed in systems of

large, slowly reorienting micelles.^{41,42} In contrast to the non-Lorentzian band shape, one often observes an exponential longitudinal relaxation due to rapid internal equilibration of the spin system (spin diffusion), and the frequency dependence of R_1 has been measured by using field cycling techniques.^{44,45}

In an alkyl chain, the ^{13}C nuclei are relaxed by the fluctuating dipole–dipole coupling to the directly bound protons. The various carbon atoms along the chain are normally resolved. Usually, one applies broadband proton decoupling, resulting in exponential longitudinal relaxation of the individual ^{13}C magnetizations, and it is possible to determine R_1 and the nuclear Overhauser enhancement of the different methylene segments. On the other hand, it is difficult to measure R_2 on ^{13}C . Therefore, ^{13}C is mainly useful for studying local chain dynamics and segmental order, since the aggregate dynamics occur on timescales which are normally long relative to the inverse ^{13}C resonance frequency.

Certain surfactants carry phosphate or ammonium polar headgroups, offering ^{31}P and ^{14}N nuclei, respectively, for relaxation studies. The phosphate ^{31}P ($I = \frac{1}{2}$) has a relatively large chemical shift anisotropy which is strongly dependent on the pH (degree of protonation), complicating the analysis of relaxation data. ^{14}N is a $I = 1$ nucleus and its relaxation is dominated by the strong quadrupolar interaction. Except for the case of quaternary ammonium groups, the magnitude and asymmetry of the quadrupolar coupling is also pH dependent, and special care has to be taken.

The most suitable nucleus for relaxation studies of surfactant systems is ^2H , which can be incorporated synthetically into the hydrocarbon chain of the surfactant molecule. Normally, one selectively labels a single methylene segment, typically one adjacent to the polar headgroup, in order to avoid resonance overlap in the spectrum. ^2H is a $I = 1$ nucleus, and the dominating interaction governing the relaxation is the strong quadrupolar interaction. For aliphatic ($\text{C}-^2\text{H}$) deuterons, the analysis is further simplified by the fact that the electric field gradient tensor has essentially cylindrical symmetry around the $\text{C}-^2\text{H}$ bond direction, resulting in a vanishing asymmetry parameter. The ease with which both R_1 and R_2 can be accurately measured, the relatively simple interaction Hamiltonian, and the sufficiently high sensitivity allowing measurements to be made at low resonance frequencies (down to 2 MHz using variable field electromagnets), give ^2H NMR relaxation a particularly important role among the different experimental tools available for studying surfactant systems.

The utility of the NMR technique as an experimental tool in surfactant science can be made apparent by comparing the strengths and weaknesses of the NMR relaxation technique with those of other experimental techniques. In comparison with other experimental methods used in studying, for example, micellar size, the NMR relaxation technique has two major advantages, both of which are associated with the fact that it is reorientational motions which are measured. One is that the relaxation, i.e. R_2 , is sensitive to small variations in micellar size. Consider, for example, a sphere for which the rotational correlation time is proportional to the cube of the radius. This can be compared with the translational self-diffusion coefficient which varies linearly with the radius. The second, and perhaps most important advantage is the fact that the rotational diffusion of particles in solution is essentially independent of interparticle interactions (electrostatic and hydrodynamic). This is in contrast to most

other techniques (such as viscosity, collective and self-diffusion, scattered light intensity, etc.) available for studying surfactant systems or colloidal systems in general. In this latter respect, NMR relaxation experiments are comparable with form factor determinations with small angle X-ray or neutron scattering experiments. A weakness of the NMR relaxation approach to aggregate size determinations, compared with form factor determinations, would be the difficulties of absolute calibration, since the transformation from information on dynamics to information on structure must be performed by means of a motional model.

3.1 Timescale Separation: The Two-Step Model

In this section we discuss a motional model^{46–48} of aggregated surfactant molecules, which involves a timescale separation of fast local and slow global motions. This model has been applied extensively to, and shown to rationalize, NMR relaxation data from aggregated surfactant systems. We discuss the model in connection with ^2H relaxation experiments, since the most extensive experimental studies have been performed on ^2H -labeled surfactants. We begin by recalling that the longitudinal (R_1) and transverse (R_2) relaxation rates of an $I = 1$ nucleus, due to the quadrupolar interaction in an isotropic solution, are given by⁴⁹

$$R_1 = \frac{3\pi^2}{40} \chi^2 [2j(\omega_0) + 8j(2\omega_0)] \quad (6a)$$

$$R_2 = \frac{3\pi^2}{40} \chi^2 [3j(0) + 5j(\omega_0) + 2j(2\omega_0)] \quad (6b)$$

where χ is the quadrupolar coupling constant, and $j(\omega_0)$ is the reduced spectral density function evaluated at the Larmor frequency ω_0 .

Based on existing knowledge of surfactant aggregate structures, Wennerström and co-workers^{46–48} suggested that the reorientational motion of surfactant molecules can be divided into: (i) fast local motions (equilibration of internal modes), which are slightly anisotropic due to the preferred orientation of the surfactant molecules; and (ii) slow isotropic motions, associated with the aggregate tumbling and the lateral diffusion of surfactant molecules within the aggregates. If these two motions occur on significantly different timescales, the fast motions generate a well-defined residual anisotropy to be averaged by the slow motions, and the spectral density can be written as a weighted sum of the fast and the slow components

$$j(\omega_0) = (1 - S^2)j_f(\omega_0) + S^2j_s(\omega_0) \quad (7)$$

where $j_f(\omega_0)$ and $j_s(\omega_0)$ are the reduced spectral density functions describing the fast and slow motions, respectively. The parameter S is often referred to as an ‘order parameter’ and is given by the average

$$S = \frac{1}{2} \langle 3 \cos \theta_{\text{MD}} - 1 \rangle_f \quad (8)$$

where θ_{MD} is the angle between the axis of the maximum component of the electric field gradient tensor and the director axis.

The situation for the case of a ^2H -labeled methylene segment of a surfactant molecule residing in a micelle is

Figure 7 Schematic illustration of the various coordinate frames considered within the two-step model, for the case of a specifically ^2H -labeled methylene segment in the surfactant hydrocarbon chain. The laboratory frame (L) is set by the direction of the external magnetic field, where Z_L is the field direction. In this frame the nuclear quadrupolar moment tensor is diagonal. The director frame (D) is associated with the micellar aggregate, where Z_D specifies the micellar surface normal. It is assumed that the fast local dynamics occur with an essentially cylindrical symmetry around Z_D . The molecular frame (M) corresponds to the principal axis of the electric field gradient tensor. For the case of a methylene segment, Z_M specifies the maximum component of the field gradient tensor, which is also cylindrically symmetric around Z_M

illustrated in Figure 7. The director axis Z_D corresponds to the micellar surface normal. The field gradient tensor is cylindrically symmetric around the C–D bond axis, with the maximum component in the bond axis direction Z_M .

In equation (7) it is also assumed that the fast motions have an effective three-fold or higher symmetry around the director. For most situations, however, one may expect an effectively cylindrical symmetry. For lower than three-fold symmetry, equation (7) must be extended to include a second-order parameter, describing the residual order in the plane perpendicular to the director. A similar extension is also necessary when the electric field gradient has a nonvanishing asymmetry parameter (for an extensive discussion, see Halle and Wennerström⁴⁸).

3.2 Frequency Dependent Relaxation Studies of Small Spherical Micelles

The fast motions, described by the spectral density function $j_f(\omega_0)$, are expected to occur on a similar timescale ($\tau_f \approx 10^{-11}$ s) as in the corresponding liquid alkane. Thus this motion is in extreme narrowing ($\tau_f \ll 1/\omega_0$) in the accessible frequency range, and we may assume that $j_f(2\omega_0) \approx j_f(\omega_0) \approx j_f(0) = 2\tau_f$, where τ_f should be considered as an effective correlation time, representing the integral over a nonexponential correlation function.

The slow motion is a combination of micelle tumbling and the lateral diffusion of surfactant molecules within the surfactant film. For spherical aggregates, this motion is described by a Lorentzian spectral density function:

$$j_s(\omega_0) = \frac{2\tau_s}{1 + (\omega_0\tau_s)^2} \quad (9)$$

where τ_s is the correlation time. The tumbling and the lateral diffusion are expected to be statistically independent, in which case the correlation function can be factorized:

$$G_s = G_t G_d = e^{-t/\tau_t} e^{-t/\tau_d} = e^{-t/\tau_s} \quad (10)$$

where subscripts t and d refer to tumbling and lateral diffusion, respectively, and the slow correlation time can be written as

$$\frac{1}{\tau_s} = \frac{1}{\tau_t} + \frac{1}{\tau_d} \quad (11)$$

The correlation time associated with the tumbling of a sphere of radius R is given by

$$\tau_t = \frac{4\pi\eta R^3}{3k_B T} \quad (12)$$

where η represents the solvent viscosity, and $k_B T$ is the thermal energy. The effect of lateral diffusion can be described in terms of diffusion on the surface of a sphere of radius R . In this case, the correlation time can be written as

$$\tau_d = \frac{R^2}{6D_{\text{lat}}} \quad (13)$$

where D_{lat} is the lateral diffusion coefficient.

With the assumptions of (i) extreme narrowing conditions for the fast motions and (ii) a Lorentzian spectral density function of the slow motion, the expressions for the relaxation rates become, with equation (7)

$$R_1 = \frac{3\pi^2}{40} \chi^2 \left\{ (1 - S^2)20\tau_f + S^2 \times \left[\frac{4\tau_s}{1 + (\omega_0\tau_s)^2} + \frac{16\tau_s}{1 + (2\omega_0\tau_s)^2} \right] \right\} \quad (14a)$$

$$R_2 = \frac{3\pi^2}{40} \chi^2 \left\{ (1 - S^2)20\tau_f + S^2 \times \left[6\tau_s + \frac{10\tau_s}{1 + (\omega_0\tau_s)^2} + \frac{4\tau_s}{1 + (2\omega_0\tau_s)^2} \right] \right\} \quad (14b)$$

Equations (14a) and (14b) have been applied in a large number of ^2H NMR relaxation studies of micellar systems. It turns out that frequency dependent relaxation studies are particularly useful for studying small spherical micelles, which typically have a radius of about 2 nm. Using the water viscosity and equation (12) we obtain $\tau_t \approx 7$ ns at room temperature (25 °C). Including the effect of lateral diffusion, a typical value of the slow correlation time is $\tau_s \approx 5$ ns. Thus, the relaxation dispersion from the slow motion occurs around ν_0

Figure 8 The variation in R_1 and R_2 with the Larmor frequency for ^2H nuclei bound to the α -methylene segment of the surfactant hexadecyltrimethylammonium chloride. The sample was an aqueous micellar solution containing 13 wt% of the surfactant. Experiments were performed at 27 °C. (Data from Söderman et al.⁵¹)

$\approx (2\pi\tau_s)^{-1} \approx 30$ MHz, which is well within the accessible Larmor frequency range for ^2H .

To investigate the applicability of the motional model, Söderman and co-workers^{50,51} studied aqueous micellar systems of alkyltrimethylammonium chloride surfactants of two different alkyl chain lengths: dodecyl and hexadecyl chains. The alkyl chains were ^2H labeled in the α -methylene segment, adjacent to the ammonium polar headgroup, and the relaxation rates R_1 and R_2 were measured in the Larmor frequency range 2–55 MHz, in order to cover the dispersion of the slow motion. The lower frequencies were obtained by using a variable field electromagnet. The results⁵¹ obtained for the hexadecyltrimethylammonium chloride micelles (concentration 13 wt%) are shown in Figure 8. The solid lines are best fits of equations (14a) and (14b) to the whole data set, using τ_f , τ_s , and S as adjustable parameters. As can be seen from Figure 8, the data are well described by a Lorentzian spectral density function superimposed on a constant offset in the investigated frequency range, thus supporting the assumption of timescale separation. The fit yielded $\tau_f = 42 \pm 1$ ps, $\tau_s = 7.6 \pm 0.4$ ns, and $S = 0.186 \pm 0.003$, where the uncertainties correspond to an approximately 80% confidence interval taking only random errors into account, and a value of $\chi = 167$ kHz was used for the quadrupolar coupling constant.

The slow correlation time was interpreted in terms of equations (11)–(13), which contain two unknown parameters, R and D_{lat} . However, D_{lat} can be measured in phases of extended surfactant films, such as bicontinuous cubic phases, and R is expected to be close to the overall length of the surfactant molecule. Using $D_{\text{lat}} \approx 1 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$, as measured in a bicontinuous cubic phase of the similar surfactant hexadecylammonium fluoride, and the radius $R = 2.37$ nm, a slow correlation time of approximately 10 ns was calculated from equations (11)–(13), which is in reasonable agreement with the experimentally determined value.

The applicability of the two-step model receives further support when comparing the S value obtained from the fit to the relaxation dispersion with that measured from quadrupolar

splittings in liquid crystalline phases formed at higher surfactant concentrations. In the liquid crystalline phases, extended surfactant aggregates are 'locked' in a crystalline array. Two very common structures are the lamellar phase, where surfactant bilayers are stacked with one-dimensional order, and the hexagonal phase, where cylindrical aggregates are packed on a two-dimensional hexagonal lattice. In these phases one has effectively frozen the slow motion, and the nuclei experience a static quadrupolar Hamiltonian $\langle \hat{H}_Q \rangle_f$ in addition to the Zeeman term, where the average is taken over the fast local motions. This results in a quadrupolar splitting of magnitude⁴⁶

$$\Delta_{\text{lam}} = \frac{3}{4} \chi |S| \quad (15)$$

in the lamellar phase with planar films. In the hexagonal phase, the rapid surfactant diffusion around the cylinder axis results in an additional averaging of the interaction by a factor of 2 and the splitting is given by

$$\Delta_{\text{hex}} = \frac{3}{8} \chi |S| \quad (16)$$

One may expect that the local motions, and hence the S value, should be similar in the liquid crystalline surfactant aggregates and the micelles in the dilute solution phase. This is in fact found to be the case. As mentioned above, the S value obtained from the fit to the relaxation dispersion (Figure 8) was found to be $S = 0.186$. A very similar value (0.192) was measured in the hexagonal phase at higher concentrations.⁵¹

3.3 Larger Aggregates: Use of the Zero Frequency Spectral Density

The small spherical micelles ($R \approx 2$ nm) can be seen as a limiting case, and in general surfactant aggregates have much larger extensions. When the size of the aggregates increases, τ_s increases as well, and the relevant relaxation dispersion moves out of the accessible frequency window. In some extreme cases, for example with long, entangled wormlike micelles, the dynamics may even move out of motional narrowing, showing slow motion effects in the NMR spectrum.⁴² However, for most micellar and microemulsion systems, the motional narrowing condition applies. In these cases, valuable information may be obtained by measuring R_1 and R_2 for ^2H -labeled surfactants at a single Larmor frequency. For larger aggregates, the relevant information on the aggregate size is contained in the zero frequency spectral density only. Assuming that the fast motions are in extreme narrowing, in which case they contribute to a constant offset of both R_1 and R_2 , it is useful to consider the difference $\Delta R = R_2 - R_1$ which then depends only on the slow motions. For the case of very slow motions, we also have $j_s(0) \gg j_s(\omega_0) \approx j_s(2\omega_0)$, and ΔR can be approximated by

$$\Delta R = \frac{9\pi^2}{40} (\chi S)^2 j_s(0) \quad (17)$$

This expression has been used to study variations in the shape of surfactant aggregates in different microemulsion

systems.^{52,53} Here, the micellar aggregates are swollen by the addition of a third component (normal micelles in aqueous solution are swollen by oil; reverse micelles in oil are swollen by water), where spherical aggregates can have radii of the order of 10 nm. Quantitative applications of equation (17) require reliable determinations of S from adjacent liquid crystalline phases. Furthermore, they require assumptions concerning the aggregate shape, and a knowledge of D_{lat} , to determine, for example, an aggregate radius of spherical aggregates. So, obviously, there are some uncertainties involved concerning the 'absolute calibration' of the method.

The situation can, however, be optimized by noting that the aggregates are formed under the constraint of a constant average interfacial area/enclosed volume ratio, set by the surfactant/internal component concentration ratio. With this constraint, the minimum aggregate size corresponds to a spherical shape. Due to the entropy of mixing, spherical aggregates, representing the minimum aggregate size, will always be stable at high dilutions, where the experiment can be calibrated. In many cases, D_{lat} is also known quite accurately from the various bicontinuous phases of the different systems.

Deviations from spherical shape can be modeled as a growth into prolate or oblate shapes. The interfacial area/enclosed volume constraint implies a constraint on the possible values of the two semiaxes describing the particle size. Halle⁵⁴ has calculated the correlation functions for the combined particle tumbling and surface diffusion of prolate and oblate particles. His results have been applied to, for example, microemulsion systems,^{52,53} focusing on the ratio $j_{s,\text{pr}}(0)/j_{s,\text{sph}}(0)$, where the subscripts pr and sph refer to prolate and spherical particles, respectively. For a given interfacial area/enclosed volume ratio, which specifies the radius R of the sphere, $j_{s,\text{pr}}(0)/j_{s,\text{sph}}(0)$ is a function of the prolate axial ratio D_{lat} , and R . Knowing D_{lat} and R from other experiments it is possible to determine the aggregate axial ratio from the relaxation experiment.

As mentioned above, the strength of the NMR relaxation technique in comparison to other (e.g. scattering) techniques for studying micelles and microemulsions is related to the fact that rotational dynamics are monitored. This has the advantages that (i) the dynamics are sensitive to small size variations, and (ii) the dynamics are essentially independent of interactions. In an extensive study of a three-component microemulsion system composed of the nonionic surfactant pentaethyleneoxide dodecyl ether, water, and decane, oil swollen micelles dispersed in water were investigated over a large concentration range.⁵²

With a nonionic surfactant, spherical aggregates are formed at lower temperatures, while the aggregates grow in size with increasing temperature.¹⁷ Figure 9 shows the variation of ΔR with temperature for two compositions, $\Phi = 0.12$ and 0.23, in the microemulsion phase.⁵² Here, $\Phi = \Phi_s + \Phi_o$ is the total volume fraction of surfactant (Φ_s) and oil (Φ_o), and the ratio $\Phi_s/\Phi_o = 0.815$ was kept constant.

The value of ΔR decreases when the temperature is decreased in the microemulsion phase and levels off at lower temperatures at a minimum value ΔR_{min} , when the aggregates have reached the limiting spherical shape, corresponding to the minimum size. Note that the minimum ΔR value is the same for the two concentrations, as is expected because the radius, dictated by Φ_s/Φ_o , should be the same. By considering

Figure 9 Variation in ${}^2\text{H}$ $\Delta R = R_2 - R_1$ with temperature of the ${}^2\text{H}$ -labeled nonionic surfactant pentaethyleneoxide dodecyl ether $[\text{CH}_3(\text{CH}_2)_{10}\text{C}^2\text{H}_2(\text{OCH}_2\text{CH}_2)_5\text{OH}]$ in a ternary system with water and decane. The ratio Φ_s/Φ_o is 0.815, where Φ_s and Φ_o are the surfactant and oil volume fractions, respectively. The concentrations are $\Phi = \Phi_s + \Phi_o = 0.12$ and 0.23 , respectively. (Data from Leaver et al.⁵²)

the reduced ΔR value, $\Delta R/\Delta R_{\min} = j_{s,\text{pr}}(0)/j_{s,\text{sph}}(0)$, it was possible to calculate the increase in the axial ratio of the aggregates with increasing temperature, assuming a growth into prolate aggregates. The variation in the axial ratio obtained is shown in Figure 10.

Very large micelles may also form in binary surfactant systems. These are long wormlike micelles which become entangled at higher concentrations, giving rise to rheological properties similar to those in polymer solutions. Such systems have been examined by means of ${}^1\text{H}$ bandshape analysis.^{41,42} The protons of the surfactant hydrocarbon chain form a very large dipolar coupled spin system, with essentially a continuum distribution of transverse relaxation rates. The distribution of relaxation rates is related to the distribution of order parameters,⁴³ which can be obtained from analyzing the bandshape in the liquid crystalline (lamellar or hexagonal)

Figure 10 Variation in the micellar axial ratio with temperature, assuming a monodisperse prolate growth, as deduced from the relaxation data in Figure 9 by using the correlation function due to Halle,⁵⁴ for the combined motion of aggregate tumbling and surface diffusion

phases, where the bandshape is associated with a continuum distribution of residual dipolar splittings.⁵⁵

Slow motions have also been studied by measuring the differential line broadening (DLB) of proton J coupled ${}^{13}\text{C}$ nuclei.⁵⁶ Here the difference in bandwidth of the different resonances in a ${}^{13}\text{C}$ multiplet can be attributed to the interplay between the dipole–dipole and chemical shift anisotropy relaxation mechanisms, and by analyzing the difference, information on the slow motion may be obtained.

3.4 Relaxation Measurements on Water and Counterion Nuclei

Relaxation measurements on water and counterion nuclei may also give information about the surfactant aggregate size and shape. Such measurements may be particularly useful in reverse micellar systems, where water and surfactant counterions are contained in small water pools covered by a surfactant monolayer. In a ${}^{23}\text{Na}$ ($I = \frac{3}{2}$) spin relaxation study of a reverse micellar system, the presence of slow motions was found to result in a biexponential free induction decay (FID).⁵⁷ Using the two transverse relaxation rates and an effective longitudinal relaxation rate, it was possible to determine all three spectral density values: $j(0)$, $j(\omega_0)$, and $j(2\omega_0)$. From the fit of the imaginary part of the FID it was also possible to determine the second-order quadrupolar dynamic shift, allowing for an additional test of the motional model invoked in the interpretation of the data.

An interesting application of water nuclei relaxation in microemulsions concerns the so-called ‘nuclear spin quenching’ studied by Carlström and Halle.⁵⁸ Here, the effect of chemical exchange of water protons, mediated by the presence of prototropic ions, H_3O^+ and OH^- , on the ${}^{17}\text{O}$ bandshape in a reverse micellar system was investigated. By careful analysis of the ${}^{17}\text{O}$ bandshape, information on the water exchange kinetics between droplets as well as the droplet size was obtained.

3.5 Surfactant Hydrocarbon Chain Conformations in Micelles

The early findings of narrow ${}^1\text{H}$ bands from the surfactant hydrocarbon chains in small spherical micelles revealed that the micellar interior is in a liquid-like state. Magnetic field dependent ${}^{13}\text{C}$ R_1 relaxation experiments confirmed those ideas, and a segmental order parameter profile, similar to that obtained from ${}^2\text{H}$ quadrupolar splittings in lipid bilayer systems, was obtained within the two-step formalism.⁵⁹ By studying the dynamics of a symmetric probe molecule solubilized in micelles, it was concluded that the micellar interior was characterized by an effective viscosity similar to that of the neat hydrocarbon.⁶⁰

Chachaty and co-workers^{40,61} have studied the enhanced relaxation rate due to the presence of paramagnetic counterions. The multivalent paramagnetic counterion is expected to be selectively adsorbed onto the charged micellar surface. Thus, by analyzing the effect on the ${}^{13}\text{C}$ relaxation along the chain, the distribution in the distance from the micellar surface could be estimated for the various methylene segments.

A conceptually similar study was reported recently by Palmas et al.⁶² Here, cross relaxation effects between ¹³C and nondirectly bonded protons were examined by two-dimensional heteronuclear Overhauser effect spectroscopy (HOESY). This study revealed the significance of intermolecular ¹H–¹³C dipolar interactions. Correlations between carbon atoms and protons belonging to different segments were observed in the lower part of the hydrocarbon chains, while they were found to be absent in the vicinity of the polar head-group, where the chain configuration is more rigid.

1 INTRODUCTION

Conducting polymers have attracted a great deal of interest because of their peculiar electrical behavior. The characterization of these materials is, of course, very important, in order to provide a background for understanding their complex nature. Many of the most important results regarding the characterization of conducting polymers have been obtained using solid state NMR, which is potentially one of the most useful techniques for determining the static and dynamic properties of conducting polymers.

This article discusses solid state NMR studies of polyacetylene; this has been the most investigated of the various conducting polymers, because it is the simplest prototype and shows most of the characteristic features of such polymers. Supplementary information on this subject can be obtained from two review articles: the review by Clark and Scott¹ is concerned with the NMR of polyacetylene, and the one by Kahol et al.² reviews the magnetic properties of polyacetylene (mainly) and other conjugated polymers (briefly).

2 UNDOPED POLYACETYLENE

Polyacetylene is typically synthesized as the *cis* isomer (1) in the form of crystalline films, and can be converted to the thermodynamically more stable *trans* isomer (2) by heating. The ¹³C CP MAS peaks of the *cis* and *trans* isomers appear at 127.7 and 137.3 ppm, respectively,³ unequivocally confirming the structural configuration of each isomer. The principal values of the *cis* and *trans* ¹³C chemical shift tensors were determined to be (218, 138, 22) and (219, 144, 47), respectively.³ The chemical shift tensor orientations were also obtained for *trans*-(CH)_x with respect to the single and double carbon-carbon bonds^{4,5} and for *cis*- and *trans*-(CH)_x with respect to the C-H bond.⁶ These chemical shift parameters (see also Kahol et al.)² reflect the local electronic structures and serve as a reference for the purpose of comparison with those of doped (CH)_x and other polyacetylenes with different structures.

A weaker line was found at about 47 ppm with an area intensity of 3.4% of that of the whole ¹³C CP MAS spectrum in 30% ¹³C-enriched *trans*-(CH)_x.³ This line was assigned to sp³ hybridized carbon atoms existing as defects in the polymer chain, which may originate from the Ziegler-Natta catalyst. These defects may interrupt the conjugated system and decrease the electrical conductivity. A similar line was also observed in the DNP-enhanced ¹³C NMR spectrum (see *Dynamic Nuclear Polarization and High-Resolution NMR of Solids*).⁷

The *cis*-*trans* thermal isomerization process has been studied by ¹³C CP MAS NMR.³ The *trans* peaks in partially isomerized (CH)_x show shielding shifts and broader linewidths with respect to the pure *trans* peak. The shifts indicate that the structure of partially isomerized (CH)_x differs from that of pure *trans*-(CH)_x, and the broad linewidths demonstrate that the structure is disordered. On the other hand, the *cis* peaks in partially isomerized (CH)_x show neither shifts nor line broadening compared with the spectrum of pristine *cis*-(CH)_x, indicating no changes in the structure of the *cis* parts. These results suggest that the isomerization proceeds inhomogeneously, probably from the surface of fibrils, with the core remaining in the regular *cis* structure.

The disordered nature of polyacetylene films prevents reliable structural determination by diffraction methods. Although conventional wide-line NMR spectra of undoped and doped polyacetylene have been observed in order to obtain structural information, no two sets of data agree.¹ Reliable second and fourth moments can be obtained using the magic echo technique, thus confining the structural possibilities to a few of many proposed structures.²

The carbon-carbon bond lengths in both *cis*- and *trans*-(CH)_x were obtained with the use of nutation NMR spectroscopy.⁸ By this approach, ¹³C Pake doublets were observed in polyacetylene polymerized from a mixture of 4% doubly ¹³C-enriched acetylene in doubly ¹³C-depleted acetylene. The proton-decoupled ¹³C nutation spectrum of a *cis* sample and the corresponding simulated spectrum are shown in Figure 1(a). The observed spectrum was well simulated by assuming the existence of only one carbon-carbon bond distance of 0.137 nm, which corresponds to a double bond length. This result strongly suggests that the Ziegler-Natta reaction leaves the original carbon pair doubly bonded in the resulting polymer. Unlike the spectrum of *cis*-(CH)_x, the spectrum of the corresponding *trans* isomer shows two overlapping Pake doublets [Figure 1(b)]. The simulation is a composite of two Pake patterns of equal intensity corresponding to bond lengths of 0.144 and 0.136 nm, which may be assigned to the single and double bonds, respectively, in *trans*-(CH)_x.

These carbon-carbon bond lengths were found to be independent of temperature in the range 4.2–300 K. Almost the same bond lengths and a C-C=C bond angle of 120.7 ± 1.5° were obtained for *trans*-(CH)_x using ¹³C two-dimensional NMR in combination with DNP.⁵

An interesting problem in *trans*-(CH)_x is the existence and diffusive motion of neutral (spin) solitons. As shown in

Figure 1 Experimental (—) and simulated (····) ^{13}C nutation NMR spectra observed at 77 K: (a) *cis*-(CH) $_x$ and (b) *trans*-(CH) $_x$. The samples were weakly enriched in ^{13}C pairs. (Reproduced by permission of The American Physical Society from C. S. Yannoni and T. C. Clarke, *Phys. Rev. Lett.*, 1983, **51**, 1991)

Figure 2, two kinds of domain can coexist, where the positions of the single and double bonds are exchanged. Between the two domains a defect occurs as a domain wall, where an electron is unpaired. Actually, the unpaired electron extends over several carbon atoms, and is considered to move along the chain. Thus, the defect is a kind of kink soliton.⁹ This is called a spin soliton or a neutral soliton, because it carries a spin but not a charge. The concentration of such a defect is known to be about 1/3000 carbon atoms. The spin density distribution over the several carbon atoms, which is associated with the solitons, has been determined using ENDOR (see *Electron–Nuclear Multiple Resonance Spectroscopy*).^{10–12}

Figure 2 Diffusive motion of a neutral (spin) soliton along the chain of *trans*-polyacetylene

The experimental evidence for the diffusive motion of neutral solitons was proposed by a ^1H NMR T_1^{-1} frequency dependence experiment. The T_1^{-1} was found to vary proportionally with $\omega^{-1/2}$ between 10 and 340 MHz.¹³ This shows that the solitons make a one-dimensional diffusive motion. The obtained diffusion rate D is about $6 \times 10^{13} \text{ rad s}^{-1}$ at room temperature. A similar frequency dependence experiment was also done using the ESR method and a somewhat smaller value of D was obtained.¹⁴ The ESR method is considered to be important because the nuclear spin diffusion process, which gives the same frequency dependence as the one-dimensional diffusive motion, is ineffective for the ESR. The diffusive motion of neutral solitons is also supported by the results of a DNP experiment.¹³

The temperature dependence of D determined experimentally has been a controversial subject. When the ^1H NMR T_1^{-1} data were directly analyzed, D was found to decrease with increasing temperature.¹⁵ This means that the soliton motion is interrupted by phonons. On the other hand, when the effect of trapping was assumed, the conclusion was reversed; D was found to increase with T^2 . This means that the solitons are assisted by phonons. Although the latter appears to be consistent with the ESR motional narrowing experiment,¹⁶ the

trapping effect should also be taken into account in interpreting the results of this experiment. From the DNP experiment a temperature dependence of $D \propto T^{1/2}$ was obtained.¹⁷ The D from μSR is almost independent of temperature.¹⁸ Extensive theoretical discussions have been carried out on the temperature variation of D .¹⁹ The D obtained from the ^{13}C NMR T_1^{-1} was found to be almost independent of frequency. This was explained by a model of confined soliton motion and a nuclear spin diffusion process.²⁰

3 DOPED POLYACETYLENE

When polyacetylene films are heavily doped with donor or acceptor ions they become metallic. This metallic nature has been demonstrated by Pauli paramagnetism, thermoelectric power, and optical absorption experiments. The maximum reported electrical conductivity reaches ca. $1 \times 10^5 \text{ S cm}^{-1}$, which is rather close to that of copper. Carbon-13 solid state NMR has played an important role in obtaining information on the electronic states of doped polyacetylene.

Initially a deshielding shift was observed with line broadening in AsF_6 -doped $(\text{CH})_x$, and there was a controversy as to whether it was a Knight shift or a chemical shift.¹ In order to provide a final answer to this question, ^{13}C spectra of acceptor-doped $(\text{CH})_x$ and donor-doped $(\text{CH})_x$ were measured.²¹ Figure 3(a) and (b) show the spectra of 7.6 mol% AsF_6 -doped *trans*-(CH) $_x$ and 9 mol% K-doped *trans*-(CH) $_x$, respectively,

Figure 3 Carbon-13 chemical shift powder patterns of: (a) *trans*-[CH(AsF $_6$) $_{0.076}$] $_x$, (b) *trans*-(CHK $_{0.09}$) $_x$. (····) *trans*-(CH) $_x$. (Reproduced by permission of Elsevier Science Ltd from T. Terao, S. Maeda, T. Yamabe, K. Akagi, and H. Shirakawa, *Solid State Commun.*, 1984, **49**, 829)

which were obtained without sample spinning. The spectrum of $\text{trans-}[\text{CH}(\text{AsF}_6)_{0.076}]_x$ clearly shows a deshielding shift with a broader width with respect to that of undoped $\text{trans-}(\text{CH})_x$; the observed deshielding shift of the center of gravity of the spectrum is 9 ppm. On the other hand, the spectrum of $\text{trans-}(\text{CHK}_{0.09})_x$ exhibits a shielding shift of 12 ppm. It is known that a ^{13}C line shows a deshielding or shielding shift of 160 ppm according to whether the π -electron density decreases or increases, respectively, by one electron per carbon. From this fact we can expect a deshielding shift of 12 ppm in $\text{trans-}[\text{CH}(\text{AsF}_6)_{0.076}]_x$ and a shielding shift of 14 ppm in $\text{trans-}(\text{CHK}_{0.09})_x$ from the resonance of undoped $\text{trans-}(\text{CH})_x$. On the other hand, the Knight shift was estimated to be 2 ppm. Both the direction and the magnitude of the observed shifts agree with the estimation of the chemical shifts, within an experimental error of 3 ppm, distinctly indicating that the observed shifts are chemical in origin. The contribution of the Knight shift is concluded to be smaller than 3 ppm, which is in agreement with the theoretical estimation.

Figure 4 shows the CP MAS spectrum of $\text{trans-}(\text{CHBr}_{0.103})_x$.²¹ The main peak composed of a broad peak and a rather sharp line superimposed on it is ascribed to the alkenic carbon atoms. The broad signal is shifted in the deshielding direction from the peak position of 137.3 ppm for undoped $(\text{CH})_x$, which is considered to be a chemical shift due to the removal of π electrons from sp^2 hybridized carbon atoms, as discussed above. The shift is smaller than the value (30–40 ppm) expected in the case when all bromine atoms of 10.3 mol% contribute to the removal of π electrons. This leads to the conclusion that only some bromine atoms contribute to charge transfer, the remaining bromine atoms adding to double bonds or substituting hydrogen atoms. The broad linewidth can be rationalized by considering that the charges on a polyacetylene chain are not homogeneously distributed, but may be positive or negative and of various magnitudes. Some theoretical studies based on the charged soliton model⁹ support this consideration, giving the observed linewidth.^{22–24} The chemical shift of the sharp peak is 137.3 ppm, in agreement with

Figure 4 Carbon-13 CP MAS spectrum of $\text{trans-}(\text{CHBr}_{0.103})_x$. The peak marked with an asterisk is a spinning sideband. (Reproduced by permission of Elsevier Science Ltd from T. Terao, S. Maeda, T. Yamabe, K. Akagi, and H. Shirakawa, *Solid State Commun.*, 1984, **49**, 829)

that of undoped $\text{trans-}(\text{CH})_x$. The result shows the existence of undoped regions in a fibril; the amount of the undoped regions can be estimated to be about 50% from the relative intensity of the sharp line. A swelling near the bottom of the sharp part of the sp^2 signal on the high frequency side is due to bromine-substituted carbon atoms and/or sp^3 -adjacent carbons.

A weaker peak can be seen at about 60 ppm, which is in the region of chemical shifts for sp^3 hybridized carbon atoms. The intensity ratio of 20% to the whole spectrum, however, cannot be explained even if all bromine atoms of 10.3 mol% are added to double bonds (it implies that the sample is an insulator). A considerable number of sp^3 carbon atoms are supposed to result from cross-linking induced by addition of bromine atoms.²¹ Cross-linking, as well as bromine addition, ought to disturb the conjugated system seriously and result in the low conductivity of bromine-doped $(\text{CH})_x$. Iodine-doped $(\text{CH})_x$ also exhibits a peak around 50 ppm.^{21,25}

The NMR of dopants is also important when investigating their electronic states. It was found that the resonance frequencies of ^7Li and ^{23}Na doped in $(\text{CH})_x$ are very close to the purely ionic values, irrespective of the dopant concentration.²⁶ This shows that these alkali metals in polyacetylene are completely ionized. On the other hand, the ^{133}Cs resonance in cesium-doped $(\text{CH})_x$ shows a peak at -200 ppm from the reference (aqueous solution of CsNO_3) at all concentrations and another peak at 12 100 ppm at room temperature for a concentration of 16 mol%.²⁶ Two-dimensional nutation NMR (see *Nutation Spectroscopy of Quadrupolar Nuclei*) of the central transition of the ^{23}Na resonance in sodium-doped $(\text{CH})_x$ was observed.²⁵ The spectrum consists of a broad line and a narrow line in the chemical shift dimension through doping levels from 2.8 to 28.8 mol%. This result shows the presence of at least two different crystal phases in sodium-doped $(\text{CH})_x$.

The temperature dependence of the electrical conductivity for doped polyacetylene is largely semiconductive, except for a small region near room temperature; this is considered to be due to the fibrillar structure of polyacetylene. The conductivity inside the fibrils would be metallic. The NMR method should be a powerful tool to pick up the inside metallic conductivity. The frequency dependence experiment of the ^1H NMR T_1^{-1} was extended to doped polyacetylene. A $\omega^{-1/2}$ law was also observed on a heavily AsF_6^- -doped sample.¹³ By applying the expression for one-dimensional diffusive motion, a conductivity of $5 \times 10^4 \text{ S cm}^{-1}$ at room temperature was obtained.

However, the temperature dependence experiment has not been very successful at detecting the metallic behavior. Even in the most recent experiment, heavily FSO_3^- , ClO_4^- , I_3^- , and K^+ -doped samples showed curious temperature dependences of T_1^{-1} , which are quite different from metallic samples.²⁷ The heavily AsF_6^- -doped sample also showed a similar behavior, which cannot be simply attributed to the metallic origin.²⁸ The curious experimental results were recently interpreted as being due to some restricted motion of residual spins.²⁷

The only exception was a Br_3 -doped sample. The metallic $T_1 T = \text{Constant}$ law was observed nearly 10 years ago.^{15,28} Recently, an aging effect was discovered on the Br_3 -doped samples.²⁷ For samples just after doping, the T_1^{-1} showed a similar curious behavior to the other dopants. However, this changed gradually. After 6 weeks the behavior of $T_1 T = \text{Constant}$ appeared, and after 6 months this changed to a

Figure 5 Temperature dependence of ^1H NMR T_1^{-1} in $[\text{CH}(\text{Br}_3^-)_{0.15}]_x$ at 50.5 MHz

bent curve as shown in Figure 5. To confirm the origin of this behavior new samples were prepared where bromine atoms were substituted or added to polyacetylene chains. Their T_1^{-1} showed the same behavior as in Figure 5. The frequency dependence obeyed a $\omega^{-1/2}$ law as shown in Figure 6. This result shows that the aging is due to the substitutional or additional effect of bromine. The reason why the metallic behavior was observed only for Br_3 as dopant is that the T_1^{-1} due to the residual spins was reduced by bromine substitution or addition, and that the metallic T_1^{-1} was instead enhanced by the reduction of conductivity. The bent curve in Figure 5 is reasonably accounted for by the one-dimensional metallic diffusive motion. The $T^{1.5}$ asymptotic line at high temperatures corresponds to T -linear resistivity due to phonon scattering. With the observed Pauli susceptibility $\chi_p \simeq 3.0 \times 10^{-6}$ emu mol^{-1} C, the conductivity at room temperature was calculated to be 2.5×10^3 S cm^{-1} .

Figure 6 Frequency dependence of ^1H NMR T_1^{-1} in $[\text{CH}_{0.91}\text{Br}_{0.11}(\text{Br}_3^-)_{0.041}]_x$ at 200 K

1 INTRODUCTION

Coupled spin relaxation is the generally accepted term for the spin–lattice relaxation of a scalar-coupled spin system such as a ^{13}C -containing methylene group, $^{13}\text{CH}_2$. It is a powerful method to probe motional dynamics in solution, particularly in molecules with internal motions such as polymers.

Nuclear spin relaxation was recognized as a powerful probe of motional dynamics since the observation of unexpectedly sharp resonance lines in liquids in the early days of magnetic resonance spectroscopy in the 1940s. These phenomena were explained almost immediately in terms of the effect of thermal motion by Bloembergen, Purcell, and Pound.¹ This sensitivity to motion has its basis in the fact that the energy of a spin state in a static magnetic field usually depends on an orientation, whether it is the orientation of a chemical shift tensor or a dipole–dipole interaction between two spins or a quadrupole coupling tensor. Orientational fluctuations, that is ‘motional dynamics’, cause fluctuations in the spin energy levels that can couple to each other or the surrounding lattice to produce the various phenomena of spin relaxation. Measurement of spin relaxation times in order to obtain information about dynamics has been widely exploited (see *Carbon-13 Relaxation Measurements: Organic Chemistry Applications*, etc.).

In the 1960s Woessner, amongst others, recognized the potential of using a series of relaxation interactions that are rigidly oriented relative to each other to obtain information about the anisotropy, or relative rates in different directions, of motion (see *Brownian Motion and Correlation Times*). The requirement of a series of independent spin systems all oriented rigidly relative to each other in a molecule is a stringent one however, and the method did not receive wide application.

In the 1970s several groups showed that a more productive approach was to use the multiplicity of interactions amongst a *single* spin system of three or more scalar-coupled spins to generate sufficient information to determine the full diffusion tensor of a small molecule^{2,3} (see *Relaxation Processes in Coupled-Spin Systems*). In addition, coupled spin relaxation has the advantage that a three spin system such as $^{13}\text{CH}_2$ can be incorporated in a flexible chain and thus provides a powerful

probe of internal motion. Application of these techniques to internal dynamics in small molecules has recently been reviewed.⁴

The basis for the method can be summarized briefly. The relaxation of dipolar coupled spins is generally described in terms of autocorrelation spectral densities which are the Fourier transforms of correlation functions relating the orientation of an internuclear dipole to itself at a later time. For multiple coupled spins, for example $^{13}\text{CH}_2$, a complete description of the relaxation also includes cross-correlation terms between *pairs* of dipolar vectors. The traditional approach has been to regard these as unimportant and, using our example, to decouple the ^1H spins to enhance the ^{13}C sensitivity. Invariably, the proton-decoupled methylene ^{13}C spin will relax with an ‘effective’ single exponential recovery law as the multiple exponential relaxation behavior of the coupled spins is obscured with the collapse of the proton-induced multiplet under decoupling.

Study of the fully coupled multiplets provides significant additional information. For a methylene group, four independent spectral densities are required to describe the relaxation, even in the extreme narrowing limit. These can be used to calculate four correlation times describing reorientation of the x , y , and z axes of a molecule fixed reference frame.

This article describes the application of coupled spin relaxation to the reorientational dynamics of polymer chains in solution. These dynamics have been of considerable interest in recent years. Technologically important properties such as elasticity, phase transition temperatures, and solution and melt viscosities are thought to be correlated with molecular motion.⁵ Thus, understanding the relationship between chain structure and chain motion is an important factor in predicting polymer properties.

Spin–lattice relaxation has been widely used to investigate such systems and, typically, in these studies the ^1H or ^{13}C T_1 values of the polymer are studied as a function of temperature and/or field strength. The results are then fitted to expressions derived from the theoretical models. Discrimination between models has been difficult, however. While experiments such as those described are very sensitive to the motional *timescales*, they lack descriptive details of the *geometry* of motion. This latter information is often needed to discriminate one model from another and can be provided by coupled spin relaxation methods.

In addition, computer simulations of the dynamics of simple polymers are now practical. Recent simulations of chain dynamics have included studies of polyethylene (PE), polyisoprene, and poly(ethylene oxide) (PEO).⁶ The Cartesian correlation times (described below) calculated from coupled spin relaxation measurements can be obtained directly from such simulated dynamics trajectories.

Coupled spin relaxation methods have now been applied to a series of linear polymers, most notably polyoxides. In the following, the theory and methods used in these studies are described and recent results are then summarized. The results show quite strikingly the dependence of dynamic properties on chain structure.

2 SPIN–LATTICE RELAXATION OF $^{13}\text{CH}_2$

As noted above, the $^{13}\text{CH}_2$ spin system makes an excellent probe of chain dynamics. The relative positions of the nuclei

in the methylene group are independent of the orientation or rotational state of the chain. Spin relaxation of the group then depends on its overall reorientation, not the motion of the three nuclei relative to each other. Dipole–dipole interactions among the ^{13}C and ^1H spins are sufficiently strong that they are the dominant relaxation mechanisms under most circumstances. These characteristics make the spin relaxation behavior itself relatively simple to interpret. In addition, there are experimental advantages to this spin system. The coupled spin relaxation can be characterized entirely from observing the ^1H coupled ^{13}C multiplet and individual ^{13}C signals are often easily resolved, even in complex samples. The ability to excite ^{13}C and ^1H spins separately makes it possible to dispense with most selective excitation experiments.

Relaxation in scalar-coupled spin systems has been described using Bloch–Redfield theory and then recasting the density matrix in terms of ‘magnetization modes’. A full description is given elsewhere and will not be repeated here except to summarize pertinent details (see *Relaxation Processes in Coupled-Spin Systems* and *Relaxation Mechanisms: Magnetization Modes*).

An energy level diagram for the AX_2 spin system (of which $^{13}\text{CH}_2$ is an example) is given in Figure 1. Application of Bloch–Redfield theory to the AX_2 spin system in the eigenstate representation yields an expression for the time evolution of the populations of the various states, N_κ ,

$$\frac{dN}{dt} = \mathbf{W}[N - N(\infty)] \quad (1)$$

where the elements of N are the diagonal members of the spin density matrix: $N_\kappa = \sigma_{\kappa\kappa} = \langle \kappa | \hat{\sigma} | \kappa \rangle$. The elements of the matrix $\mathbf{W}$ are a subset of the full Redfield matrix, $W_{\kappa\lambda} = R_{\kappa\kappa\lambda\lambda}$, and may be considered as simple transition probabilities.

For convenience magnetization modes, ν , corresponding to a maximum number of observables are constructed by taking linear combinations of the diagonal density matrix elements. Thus

$$\nu_\kappa = \sum_\lambda T_{\kappa\lambda} N_\lambda \quad \text{or} \quad \mathbf{\nu} = \mathbf{T}\mathbf{N} \quad (2)$$

where $T_{\kappa\lambda}$ are the elements of the transformation matrix. If $\mathbf{\Gamma} = \mathbf{T}\mathbf{W}\mathbf{T}^{-1}$, then

$$\frac{d\mathbf{\nu}}{dt} = \mathbf{\Gamma}[\mathbf{\nu} - \mathbf{\nu}(\infty)] \quad (3)$$

As line intensities depend on the difference between diagonal density matrix elements, the magnetization modes can also be expressed as combinations of line intensities. The members of a convenient set of modes for the AX_2 spin system which are observable in isotropic solution are:

$$\left. \begin{aligned} {}^a\nu_A &= \frac{1}{k_A}(L_1 + L_2 + L_3) \\ {}^a\nu_X &= \frac{1}{k_X}(L_4 + L_5) \\ {}^a\nu_{+-+} &= \frac{1}{k_A}(L_1 - L_2 + L_3) \\ {}^a\nu_{\pm\mp} &= \frac{1}{k_X}(L'_4 - L''_4 - L'_5 + L''_5) \\ &= \frac{1}{k_X}(L_1 - 2L'_2 + L_3) \\ {}^s\nu_{+0-} &= \frac{1}{k_A}(L_1 - L_3) = \frac{1}{k_X}(L_4 - L_5) \end{aligned} \right\} \quad (4)$$
